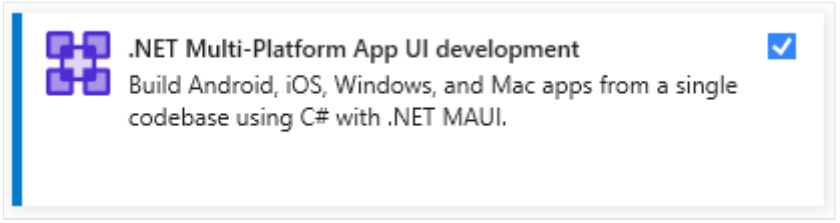
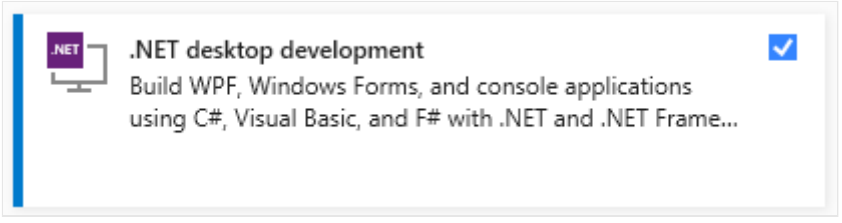
- .NET Multi-platform App UI development installed (for iOS, Android, Mac Catalyst development).



- .NET desktop development installed (for Gtk, Wpf, and Linux Framebuffer development)



Finalize your environment

1. Open a command-line prompt, Windows Terminal if you have it installed, or else Command Prompt or Windows Powershell from the Start Menu.

2. Install or update the `uno-check` tool:

   - Use the following command:

     .NET CLI

     ```
     dotnet tool install -g uno.check
     ```

   - To update the tool, if you already have previously installed an older version:

     .NET CLI

     ```
     dotnet tool update -g uno.check
     ```

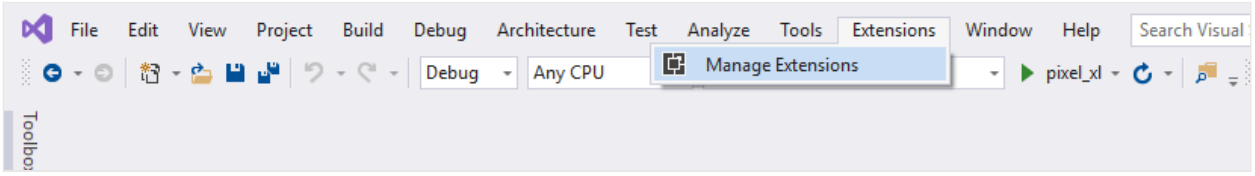
3. Run the tool with the following command:

   ```
   uno-check
   ```

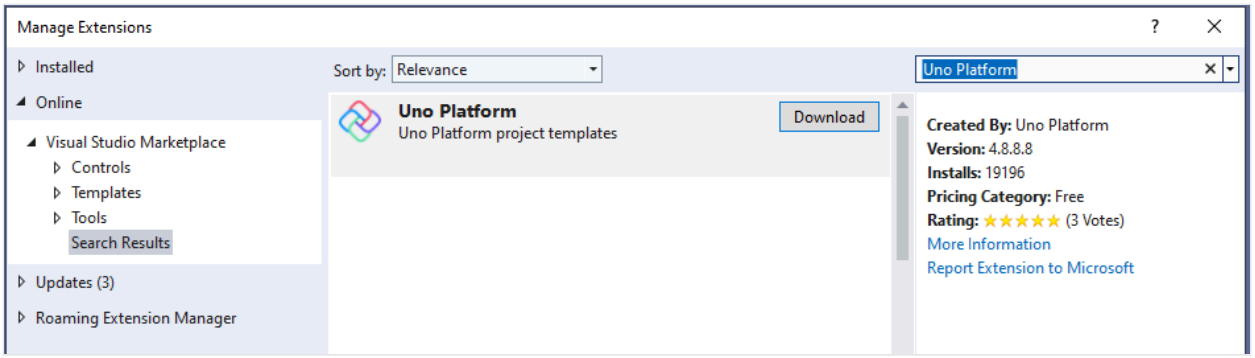
4. Follow the instructions indicated by the tool. Because it needs to modify your system, you may be prompted for elevated permissions.

Install the Uno Platform solution templates

Launch Visual Studio, then click `Continue without code`. Click `Extensions` -> `Manage Extensions` from the Menu Bar.



In the Extension Manager expand the **Online** node and search for `Uno`, install the `Uno Platform` extension, or download it from the Visual Studio Marketplace, then restart Visual Studio.

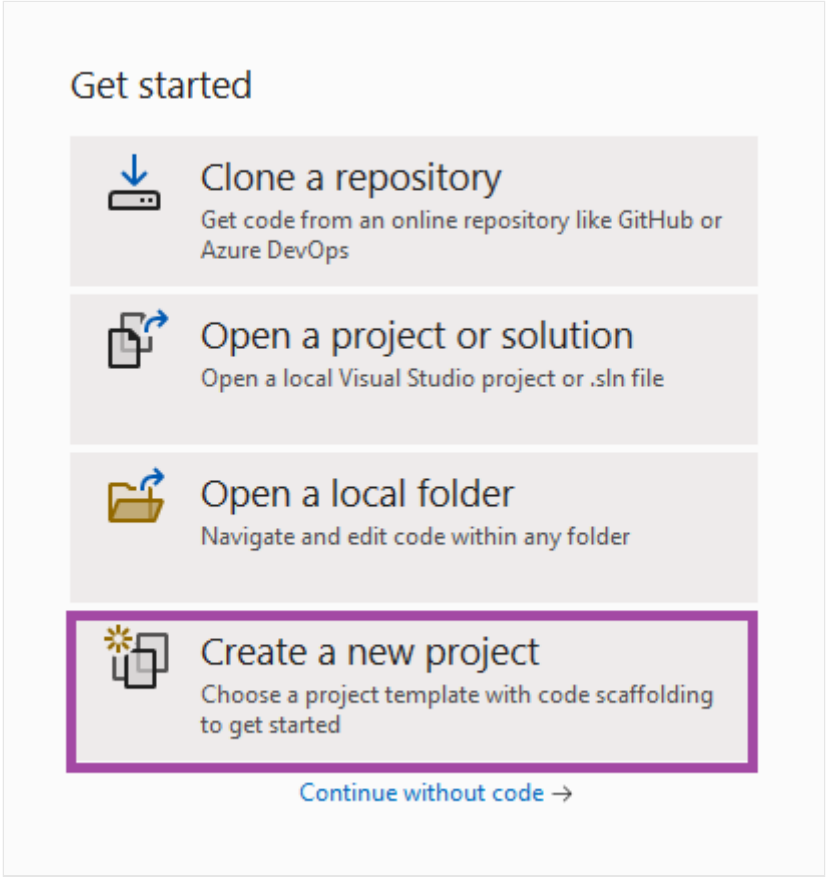


Create an application

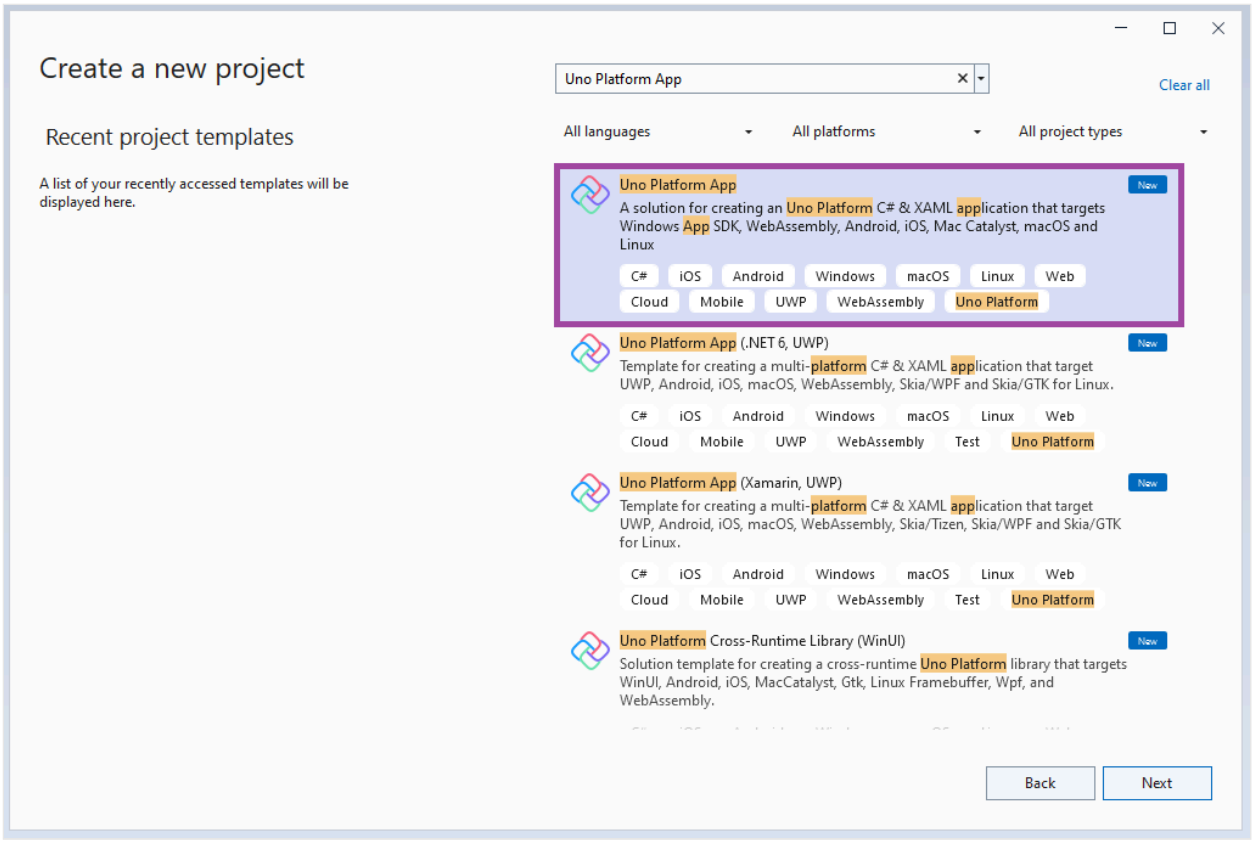
Now that we are ready to create a multi-platform application, the approach we'll take is to create a new Uno Platform application. We will copy XAML code from the previous tutorial's Hello World WinUI 3 project into our multi-platform project. This is possible because Uno Platform lets you reuse your existing codebase. For features dependent on OS APIs provided by each platform, you can easily make them work over time. This approach is especially useful if you have an existing application that you want to port to other platforms.

Soon enough, you will be able to reap the benefits of this approach, as you can target more platforms with a familiar XAML flavor and the codebase you already have.

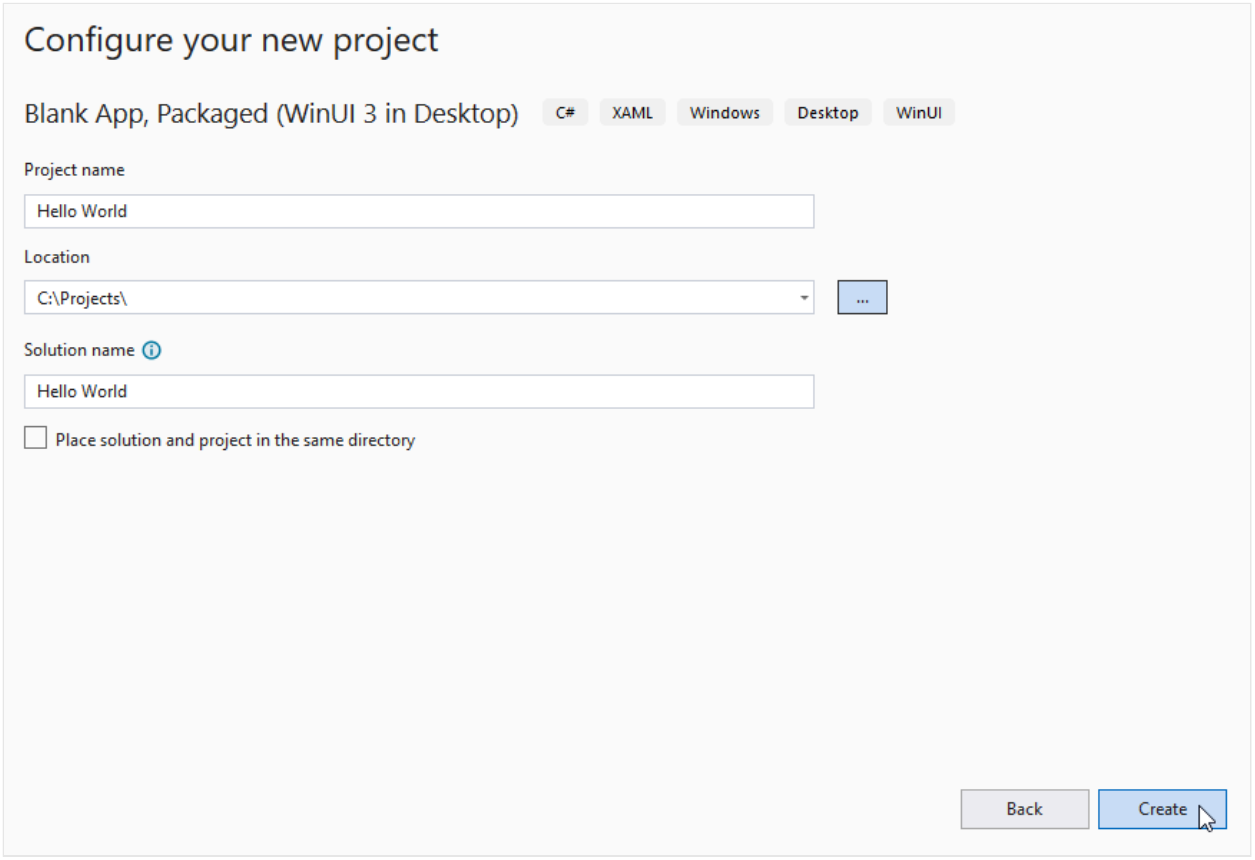
Open Visual Studio and create a new project via `File` > `New` > `Project`:



Search for Uno and select the Uno Platform App project template:

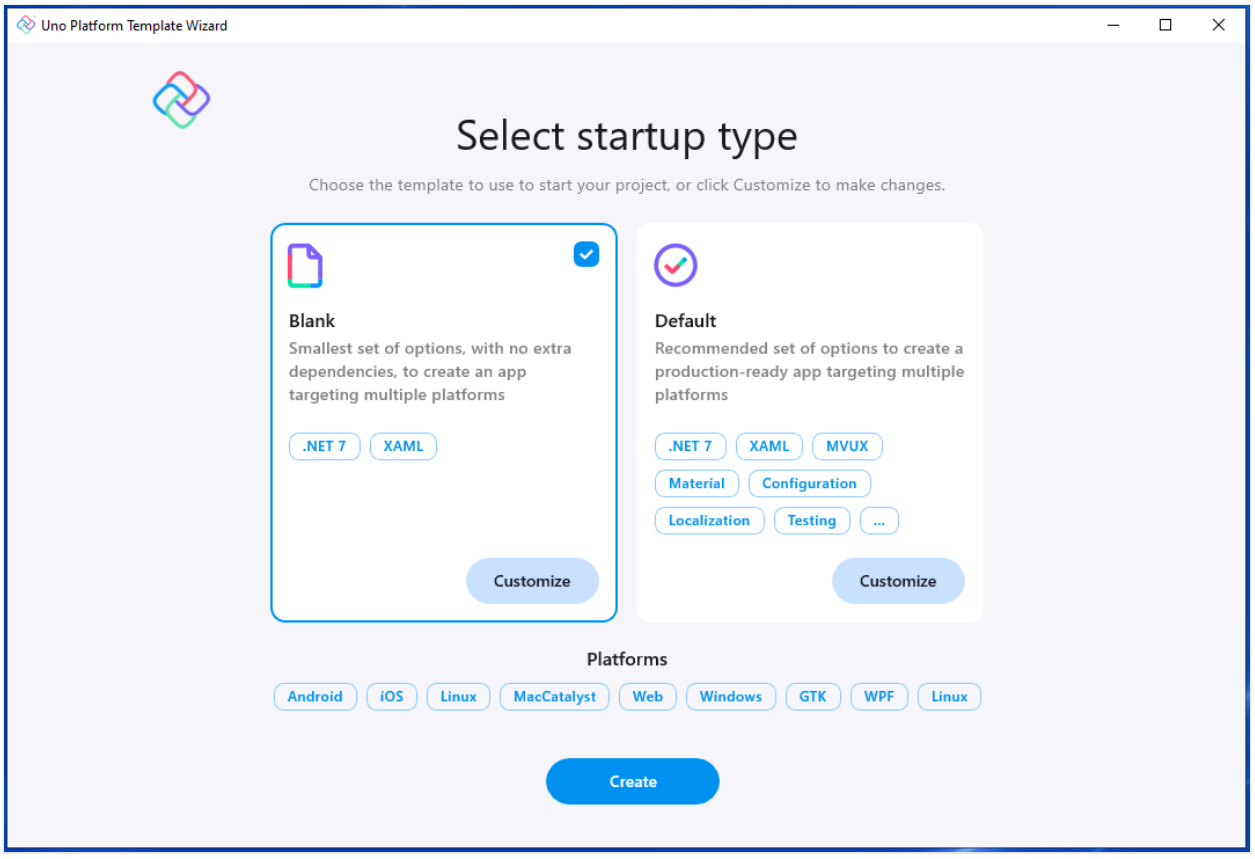


Specify a project name, solution name, and directory. In this example, our Hello World MultiPlatform project belongs to a Hello World MultiPlatform solution, which will live in C:\Projects:



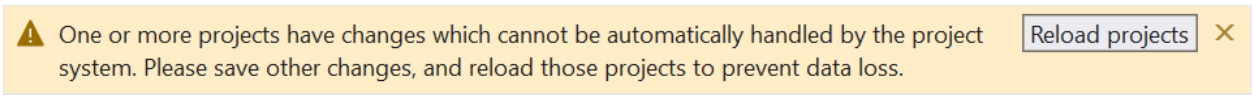
Create a new C# solution using the **Uno Platform App** type from Visual Studio's **Start Page**. To avoid conflicting with the code from the previous tutorial, we'll give this solution a different name, "Hello World Uno".

Now you'll choose a base template to take your Hello World application multi-platform. The Uno Platform App template comes with two preset options that allow you to quickly get started with either a Blank solution or the Default configuration which includes references to the Uno.Material and Uno.Toolkit libraries. The Default configuration also includes Uno.Extensions which is used for dependency injection, configuration, navigation, and logging, and it uses MVUX in place of MVVM, making it a great starting point for rapidly building real-world applications.



To keep things simple, select the **Blank** preset. Then, click the **Create** button. Wait for the projects to be created and their dependencies to be restored.

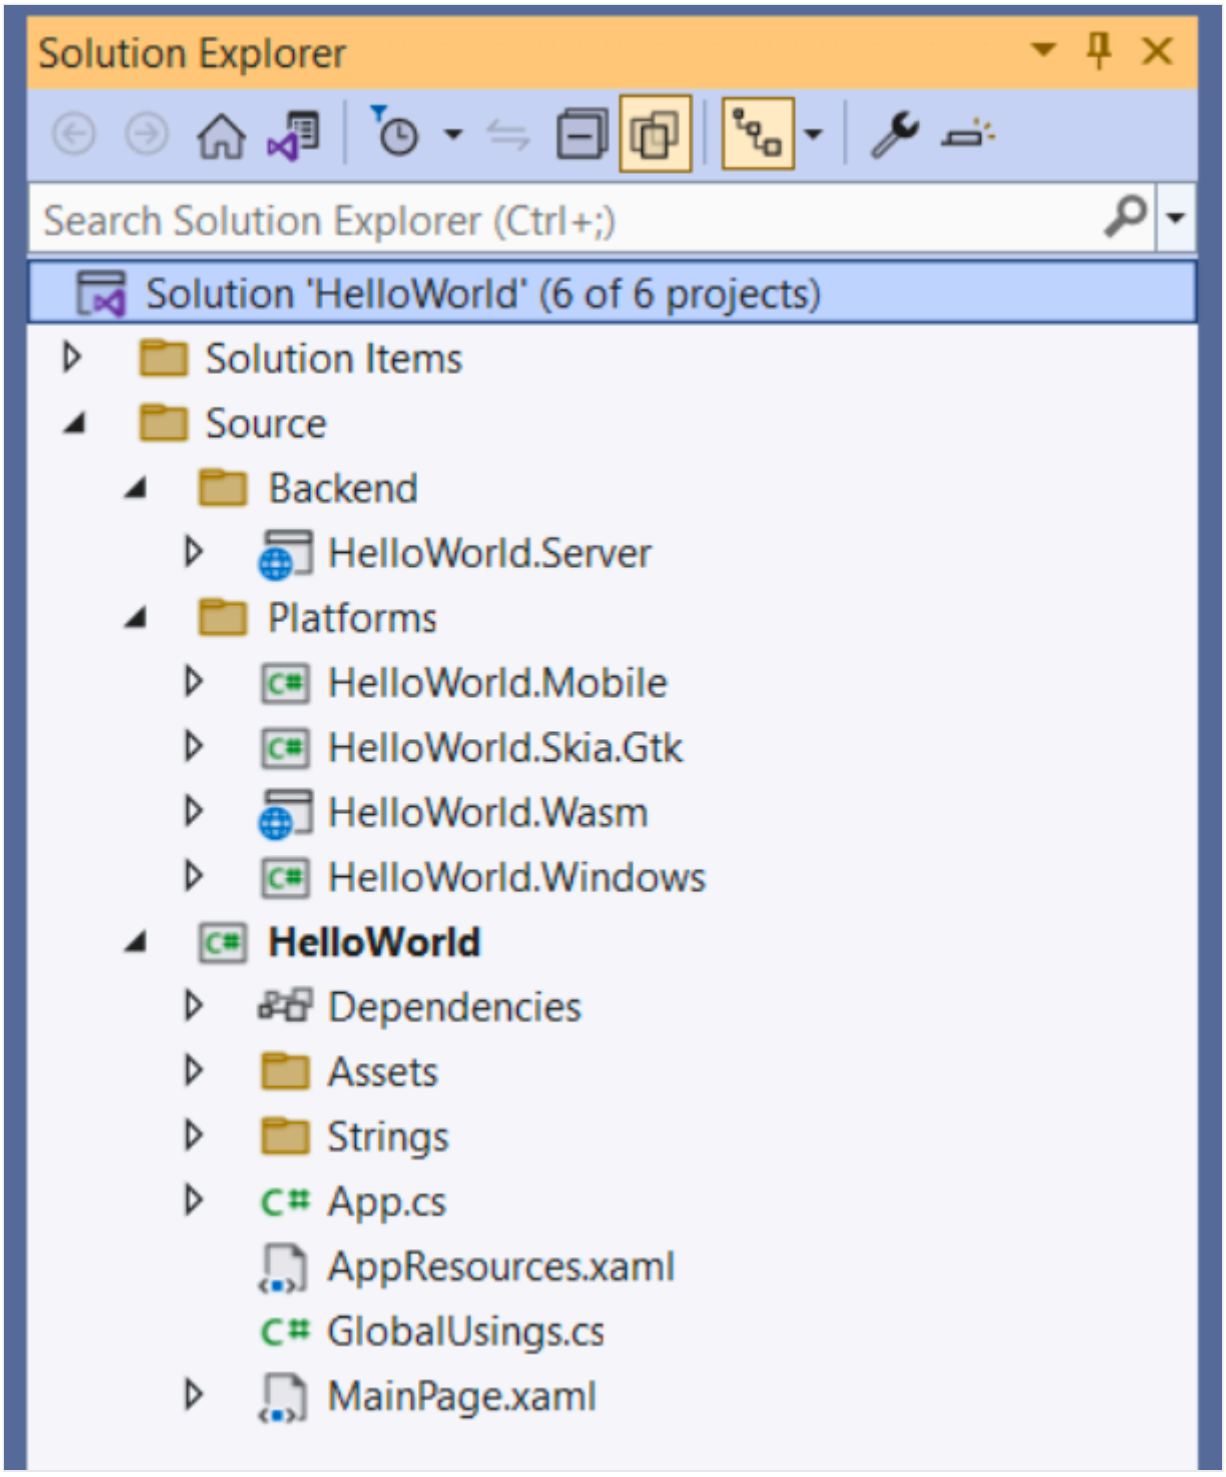
A banner at the top of the editor may ask to reload projects, click **Reload projects**:



Building your app

Now that you've generated the functional starting point of your multi-platform WinUI application, you can copy markup into it from the Hello World WinUI 3 project outlined in the previous tutorial.

You should see the following default file structure in your Solution Explorer:



Make sure Visual Studio has your WinUI 3 project open, then copy the child XAML elements from `MainWindow.xaml` in the WinUI 3 project to your `MainPage.xaml` file in the Uno Platform project. The `MainPage` view XAML should look like this:

XML

```
<Page x:Class="HelloWorld.MainPage"
   xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
   xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
   xmlns:local="using:HelloWorld"
   xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
```

```
    xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
    mc:Ignorable="d"
    Background="{ThemeResource ApplicationPageBackgroundThemeBrush}">

        <!-- Below is the code you copied from MainWindow: -->
        <StackPanel Orientation="Horizontal"
                    HorizontalAlignment="Center"
                    VerticalAlignment="Center">
            <TextBlock x:Name="myText"
                       Text="Hello world!"
                       Foreground="Red"/>
        </StackPanel>
</Page>
```

Launch the HelloWorld.Windows target. Observe that this WinUI app is identical to the previous tutorial.

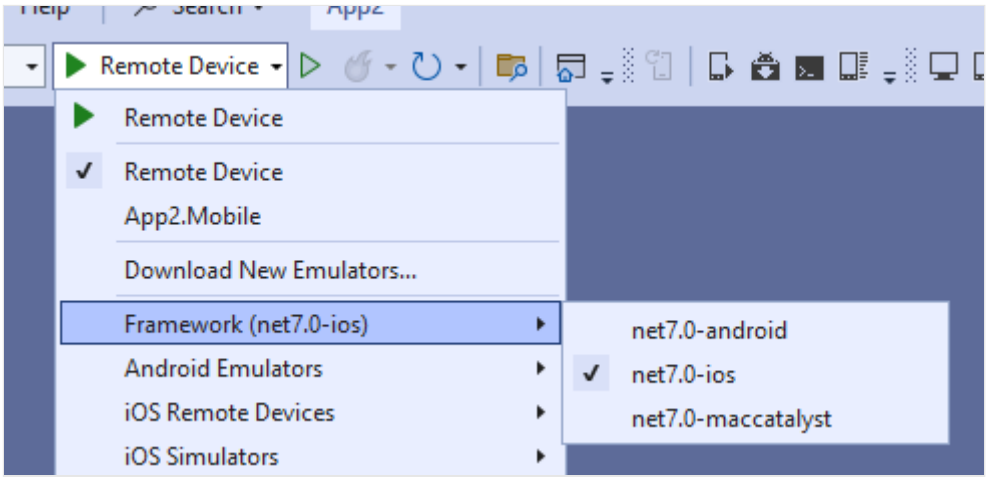
You can now build and run your app on any of the supported platforms. To do so, you can use the debug toolbar drop-down to select a target platform to deploy:

- To run the **WebAssembly** (Wasm) head:
  - Right-click on the `HelloWorld.Wasm` project, select **Set as startup project**
  - Press the `HelloWorld.Wasm` button to deploy the app
  - If desired, you can use the `HelloWorld.Server` project as an alternative

- To debug for **iOS**:

  - Right-click on the `HelloWorld.Mobile` project, select **Set as startup project**

  - In the debug toolbar drop-down, select an active iOS device or the simulator. You'll need to be paired with a Mac for this to work.



- To debug for **Mac Catalyst**:
  - Right-click on the `HelloWorld.Mobile` project, select **Set as startup project**

    - In the debug toolbar drop-down, select a remote macOS device. You'll need to be paired with one for this to work.

- To debug the **Android** platform:
    - Right-click on the `HelloWorld.Mobile` project, select **Set as startup project**
    - In the debug toolbar drop-down, select either an active Android device or the emulator
        - Select an active device in the "Device" sub-menu

- To debug on **Linux** with **Skia GTK**:
    - Right-click on the `HelloWorld.Skia.Gtk` project, and select **Set as startup project**
    - Press the `HelloWorld.Skia.Gtk` button to deploy the app

Now you're ready to start building your multi-platform application!

Create your first WinUI 3 (Windows App SDK) project

Article • 11/21/2024

In this topic we'll see how to use Visual Studio to create a new Windows App SDK project for a C# .NET or C++ app that has a WinUI 3 user interface (UI). We'll also take a look at some of the code in the resulting project, what it does, and how it works.

Links to full installation details are in the steps below. We recommend that you install and target the latest Stable release of the Windows App SDK (see Stable channel release notes).

> **Tip**
>
> No matter what version of the Windows App SDK you choose to install and target (or what version of Visual Studio you use), it's important to check any *limitations and known issues* in the release notes for that version (see **Windows App SDK release channels**). By knowing about any *limitations and known issues* for your version of the Windows App SDK, you'll be able to work around them should you run into any of them while following along with the steps in this topic.
>
> If you encounter any other issues, then you'll likely find info about them in GitHub issues, or on the **Discussions tab**, of the **WindowsAppSDK** GitHub repo; or via an online search.

> **Important**
>
> If you're working on a UWP app, then refer to **Migrate from UWP to the Windows App SDK**.

Packaged, unpackaged, and packaged with external location

Packaging is an important consideration of any Windows App SDK project. For more info about your packaging options, see Advantages and disadvantages of packaging your app.

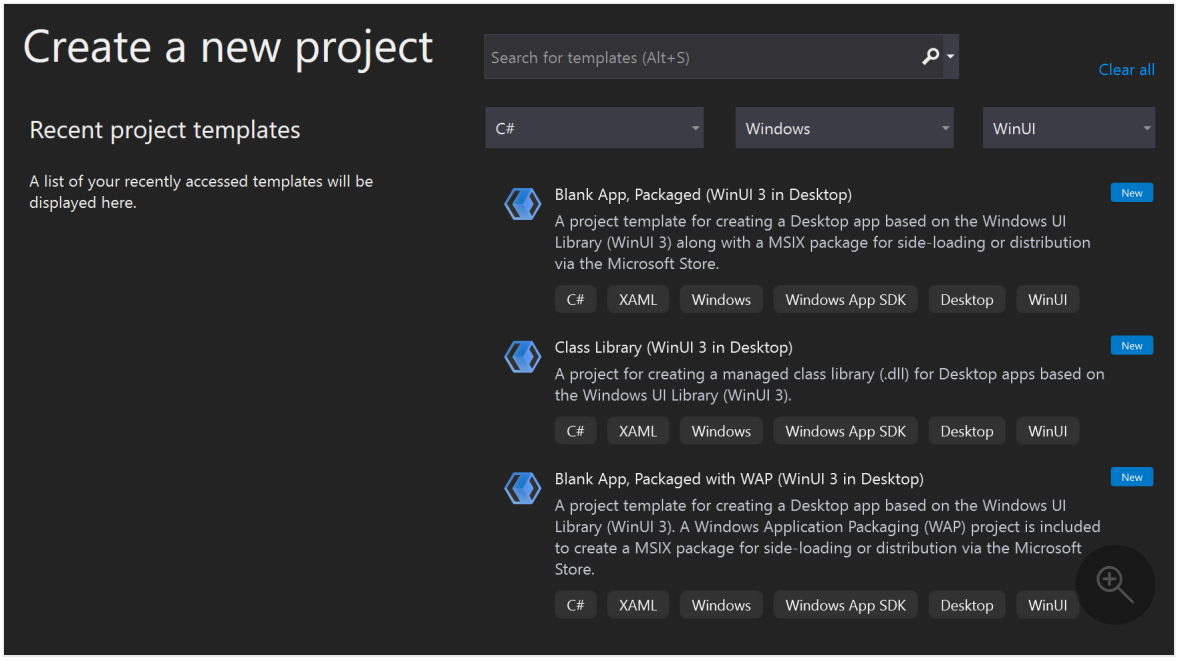
Packaged: Create a new project for a packaged C# or C++ WinUI 3 desktop app

1. To set up your development computer, see Install tools for the Windows App SDK.

2. In Visual Studio, select **File** > **New** > **Project**.

3. In the **New Project** dialog's drop-down filters, select **C#** or **C++**, **Windows**, and **WinUI**, respectively.

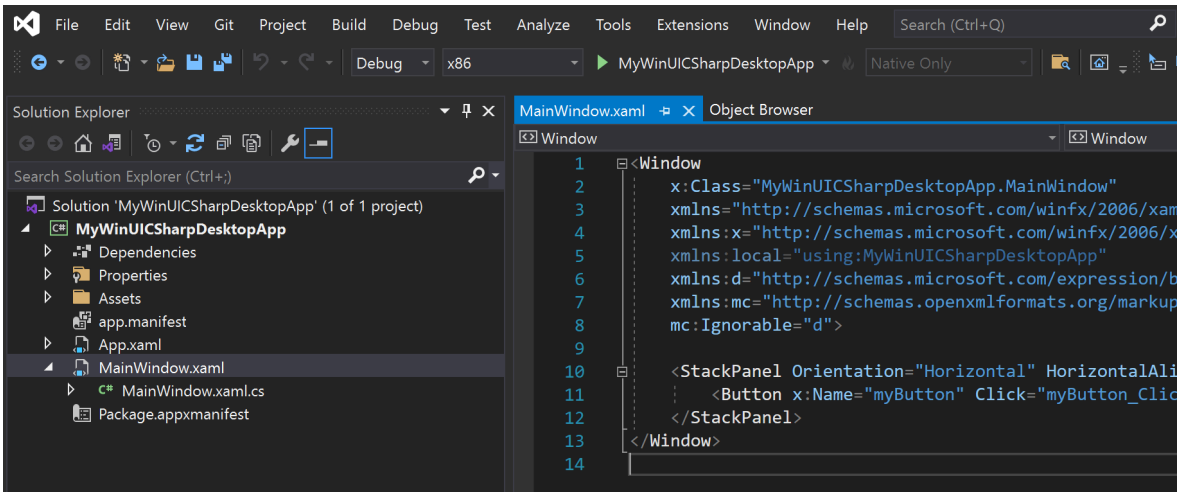
4. Select the **Blank App, Packaged (WinUI 3 in Desktop)** project template, and click **Next**. That template creates a desktop app with a WinUI 3-based user interface. The generated project is configured with the package manifest and other support needed to build the app into an MSIX package (see What is MSIX?). For more information about this project template, see Package your app using single-project MSIX.



5. Enter a project name, choose any other options as desired, and click **Create**.

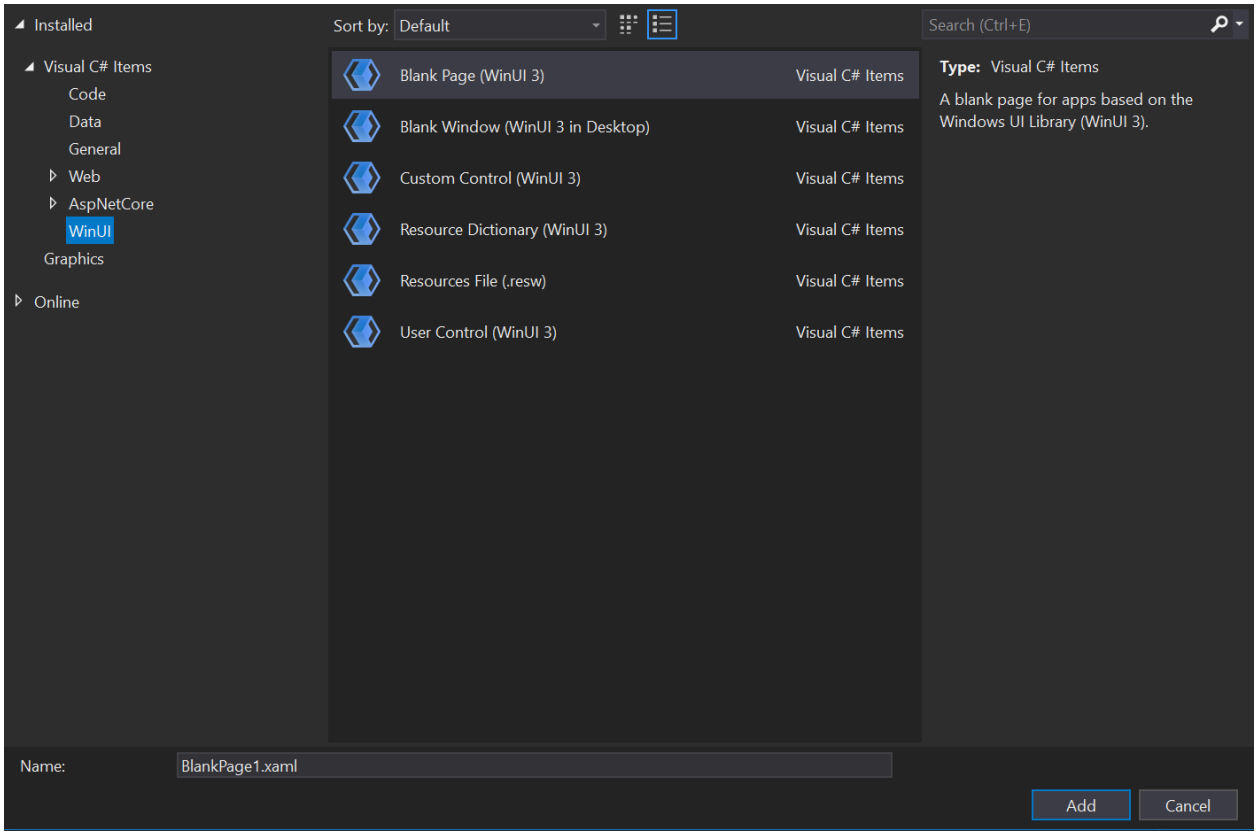
   The project that Visual Studio generates contains your app's code. The **App.xaml** file and code-behind file(s) define an **Application**-derived class that represents your running app. The **MainWindow.xaml** file and code-behind file(s) define a **MainWindow** class that represents the main window displayed by your app. Those classes derive from types in the **Microsoft.UI.Xaml** namespace provided by WinUI 3.

   The project also includes the package manifest for building the app into an MSIX package.



6. Press F5 or use the **Debug** > **Start Debugging** menu option to build and run your solution on your development computer and confirm that the app runs without errors.

The Blank App template creates a simple app with a single window for your content. Apps are typically more complex, and you'll want to add elements as your app progresses, like new windows, pages, or custom user controls. For more details about the available items, and instructions for how to add them, see WinUI 3 templates in Visual Studio.



Unpackaged: Create a new project for an unpackaged C# or C++ WinUI 3 desktop app

> **ⓘ Important**
>
> Beginning in the Windows App SDK 1.0, the default approach to loading the Windows App SDK from an app packaged with external location or an unpackaged app is to use *auto-initialization* via the `<WindowsPackageType>` project property (as well as making additional configuration changes). For the steps involved in auto-initialization in the context of WinUI 3 project, continue reading this section. Or, if you have an existing project that's not WinUI 3, then see **Use the Windows App SDK in an existing project**.

1. To set up your development computer, see Install tools for the Windows App SDK.
2. Download and run the latest *installer* for the Windows App SDK from Downloads for the Windows App SDK. That will install the runtime package dependencies required to run and deploy an app packaged with external location or an unpackaged app on the target device (see Windows App SDK deployment guide for framework-dependent apps packaged with external location or unpackaged).
3. **C++**. Install the Microsoft Visual C++ Redistributable (VCRedist) appropriate for the architecture of the target device.

   - The latest version of the VCRedist is compatible with the latest Visual Studio generally-available (GA) release (that is, not preview), as well as all versions of Visual Studio that can be used to build Windows App SDK binaries.
   - Insider builds of Visual Studio might have installed a later version of the VCRedist, and running the public version will then fail with this error (which you can ignore): **Error 0x80070666: Cannot install a product when a newer version is installed.**

   > **ⓘ Note**
   >
   > If you don't have the VCRedist installed on the target device, then dynamic links to `c:\windows\system32\vcruntime140.dll` fail. That failure can manifest to end users in various ways.

4. In Visual Studio, select **File** > **New** > **Project**.
5. In the New Project dialog's drop-down filters, select **C#** or **C++**, **Windows**, and **WinUI**, respectively.

6. You need to start with a packaged project in order to use XAML diagnostics. So select the **Blank App, Packaged (WinUI 3 in Desktop)** project template, and click **Next**.

   > **ⓘ Important**
   >
   > Make sure that the project you just created is targeting the version of the Windows App SDK that you installed with the *installer* in step 2. To do that, in Visual Studio, click **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution...** > **Updates**. And if necessary update the reference to the *Microsoft.WindowsAppSDK* NuGet package. You can see which version is installed on the **Installed** tab.

7. Add the following property to your project file—either your `.csproj` (C#) or `.vcxproj` (C++) file. Put it inside the **PropertyGroup** element that's already there (for C++, the element will have `Label="Globals"`):

   XML

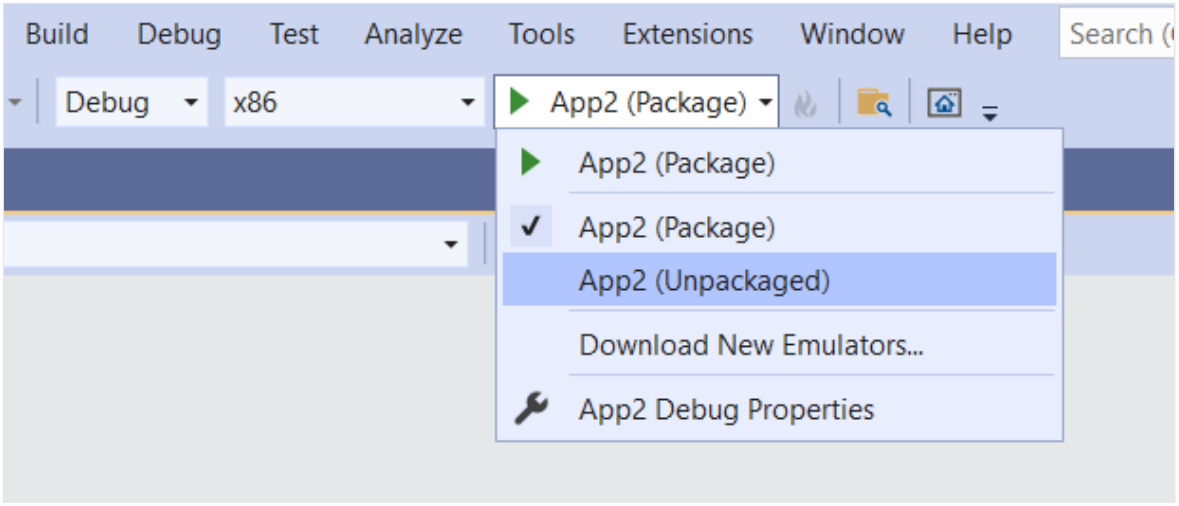
   ```
   <Project ...>
     ...
     <PropertyGroup>
       ...
       <WindowsPackageType>None</WindowsPackageType>
       ...
     </PropertyGroup>
     ...
   </Project>
   ```

8. **C++**. In your C++ project (`.vcxproj`) file, inside the **PropertyGroup** element that's already there, set the *AppxPackage* property to *false*:

   XML

   ```
   <Project ...>
     ...
     <PropertyGroup Label="Globals">
       ...
       <AppxPackage>false</AppxPackage>
       ...
     </PropertyGroup>
     ...
   </Project>
   ```

9. **C#**. To start a C# app from Visual Studio (either **Debugging** or **Without Debugging**), select the *Unpackaged* launch profile from the **Start** drop-down. If the *Package* profile is selected, then you'll see a deployment error in Visual Studio. This step isn't necessary if you start the application (`.exe`) from the command line or from Windows File Explorer.



10. Build and run.

The bootstrapper API

Setting the `<WindowsPackageType>None</WindowsPackageType>` project property causes the *auto-initializer* to locate and load a version of the Windows App SDK version that's most appropriate for your app.

If you have advanced needs (such as custom error handling, or to load a specific version of the Windows App SDK), then you can instead call the bootstrapper API explicitly. For more info, see Use the Windows App SDK runtime for apps packaged with external location or unpackaged, and Tutorial: Use the bootstrapper API in an app packaged with external location or unpackaged that uses the Windows App SDK.

For more info about the bootstrapper, see Deployment architecture and overview for framework-dependent apps.

A look at the code in the project template

In this walkthrough, we used the **Blank App, Packaged (WinUI 3 in Desktop)** project template, which creates a desktop app with a WinUI 3-based user interface. Let's take a look at some of the code that comes with that template, and what it does. For more info on available WinUI 3 project and item templates, see WinUI 3 templates in Visual Studio.

The app's entry point

When the Windows operating system (OS) runs an app, the OS begins execution in the app's *entry point*. That entry point takes the form of a **Main** (or **wWinMain** for C++/WinRT) function. Ordinarily, a new project configures that function to be auto-generated by the Visual Studio build process. And it's hidden by default, so you don't need to be concerned with it. But if you *are* curious for more info, then see Single-instancing in Main or wWinMain.

The App class

The app as a whole is represented by a class that's typically called simply **App**. That class is defined in **App.xaml** and in its code-behind file(s) (`App.xaml.cs`, or `App.xaml.h` and `.cpp`). **App** is derived from the WinUI 3 **Microsoft.UI.Xaml.Application** class.

The generated code in the entry point creates an instance of **App**, and sets it running.

In the constructor of **App**, you'll see the **InitializeComponent** method being called. That method essentially parses the contents of **App.xaml**, which is XAML markup. And that's important because **App.xaml** contains merged resources that need to be resolved and loaded into a dictionary for the running app to use.

Another interesting method of **App** is **OnLaunched**. In there we create and activate a new instance of the **MainWindow** class (which we'll look at next).

The MainWindow class

The main window displayed by the app is of course represented by the **MainWindow** class. That class is defined in **MainWindow.xaml** and in its code-behind file(s) (`MainWindow.xaml.cs`, or `MainWindow.xaml.h` and `.cpp`). **MainWindow** is derived from the WinUI 3 **Microsoft.UI.Xaml.Window** class.

The constructor of **MainWindow** calls its own **InitializeComponent** method. Again, its job is to turn the XAML markup inside **MainWindow.xaml** into a graph of user interface (UI) objects.

In **MainWindow.xaml** you'll see the basic layout of **MainWindow**. At the layout root is a dynamic panel called a **Microsoft.UI.Xaml.Controls.StackPanel**. For more info about layout panels, see Layout panels.

Inside that **StackPanel** is a **Microsoft.UI.Xaml.Controls.Button**. And that **Button** uses the markup `Click="myButton_Click"` to declaratively hook up an event handler method for

the **Click** event.

That method is named **myButton_Click**, and you can find the implementation of that method in `MainWindow.xaml.cs`, or in `MainWindow.xaml.cpp`. In it, the content of the button is changed from the default "Click Me" to "Clicked".

C++. If you created a C++ project, then you'll also see a `MainWindow.idl` file. For more info, see the C++/WinRT documentation. XAML controls; bind to a C++/WinRT property is a good place to start learning about the purpose and usage of `.idl` files.

Next steps

This topic showed how to create a Visual Studio project for a packaged or an unpackaged app. For an example of adding functionality to such an app, see Tutorial: Create a simple photo viewer with WinUI 3. That topic walks through the process of building a simple app to display photos.

Then, to continue your development journey with the Windows App SDK, see Develop Windows desktop apps.

Create a WinUI 3 app using Preview and Experimental channels of the Windows App SDK

Article • 10/24/2022

The Windows App SDK includes WinUI 3 project templates that enable you to create desktop apps with an entirely WinUI-based user interface. When you create apps using these project templates, the entire user interface of your application is implemented using windows, controls, and other UI types provided by WinUI 3. For a complete list of the project templates, see WinUI 3 templates in Visual Studio.

Using the Windows App SDK Stable version: To build a WinUI 3 app using the stable version of the Windows App SDK, see Create your first WinUI 3 project.

Prerequisites

To use the WinUI 3 project templates described in this article, configure your development computer and install the Windows App SDK extension for Visual Studio. For details, see Install tools for preview and experimental channels of the Windows App SDK.

> **Note**
>
> Certain fundamental WinRT types including CoreWindow, ApplicationView, CoreApplicationView CoreDispatcher, and their dependencies are not available in desktop apps. These types were designed specifically for UI scenarios in UWP apps, and they do not behave properly in desktop apps due to threading models and other platform differences. For more information including recommended alternative APIs, see Windows Runtime APIs not supported in desktop apps.

Instructions for WinUI 3 packaged desktop apps

To create a WinUI 3 application with MSIX packaging, choose from one of the following sets of instructions depending on the project language and the version of the Windows App SDK you have installed.

C# with 1.0 Preview 3

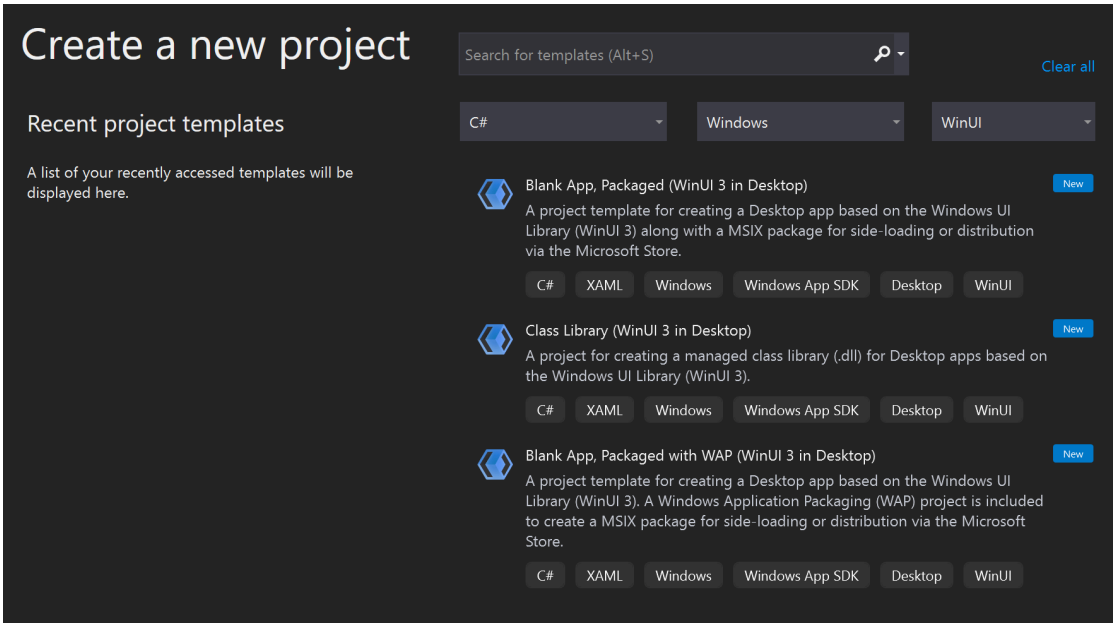
To create a WinUI 3 desktop app with C# using Windows App SDK 1.0 Preview 3:

1. In Visual Studio, select **File** -> **New** -> **Project**.
2. In the project drop-down filters, select **C#**, **Windows**, and **WinUI**, respectively.
3. Select one of the following project types and click **Next**.

    - **Blank App, Packaged (WinUI 3 in Desktop)**: Creates a desktop C# .NET app with a WinUI-based user interface. The generated project is configured with the package manifest and other support needed to build the app into an MSIX package without the use of a separate packaging project. For more information about this project type, see Package your app using single-project MSIX.

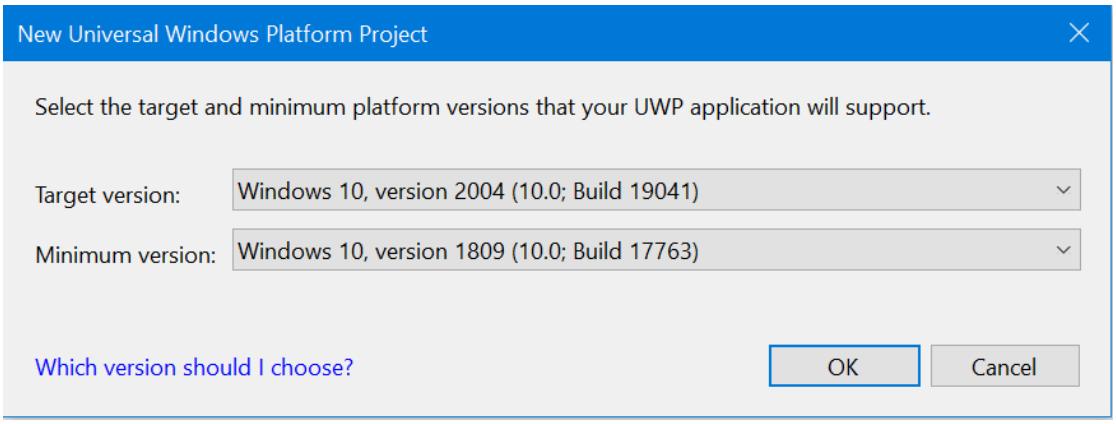
        > **Note**
        >
        > If you installed the Windows App SDK 1.0 Preview 2 with Visual Studio 2019, this project template has a known issue that results in a build error. To resolve this issue, install the Single-project MSIX Packaging Tools for Visual Studio 2019 VSIX extension after you install the Windows App SDK 1.0 Preview 2.

    - **Blank App, Packaged with WAP (WinUI 3 in Desktop)**: Creates a desktop C# .NET app with a WinUI-based user interface. The generated solution includes a separate Windows Application Packaging Project that is configured to build the app into an MSIX package.



4. Enter a project name, choose any other options as desired, and click **Create**.

5. In the following dialog box, set the **Target version** to Windows 10, version 2004 (build 19041) and **Minimum version** to Windows 10, version 1809 (build 17763) and then click **OK**.



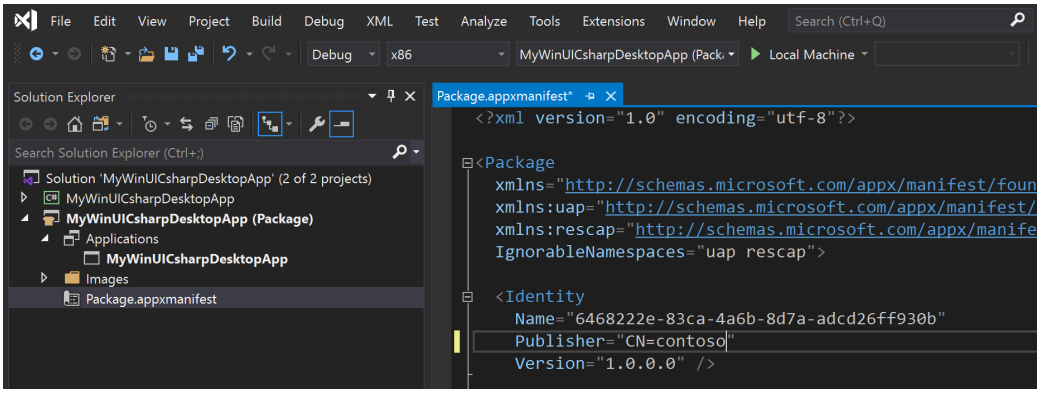
6. At this point, Visual Studio generates one or more projects:

   - ***Project name*** **(Desktop)**: This project contains your app's code. The **App.xaml** file and **App.xaml.cs** code-behind file define an `Application` class that represents your app instance. The **MainWindow.xaml** file and **MainWindow.xaml.cs** code-behind file define a `MainWindow` class that represents the main window displayed by your app. These classes derive from types in the **Microsoft.UI.Xaml** namespace provided by WinUI.

     If you used the **Blank App, Packaged (WinUI 3 in Desktop)** project template, this project also includes the package manifest for building the app into an MSIX package.

   - ***Project name*** **(Package)**: This project is generated only if you use the **Blank App, Packaged with WAP (WinUI 3 in Desktop)** project template. This project is a Windows Application Packaging Project that is configured to build the app into an MSIX package. This project contains

the package manifest for your app, and it is the startup project for your solution by default.

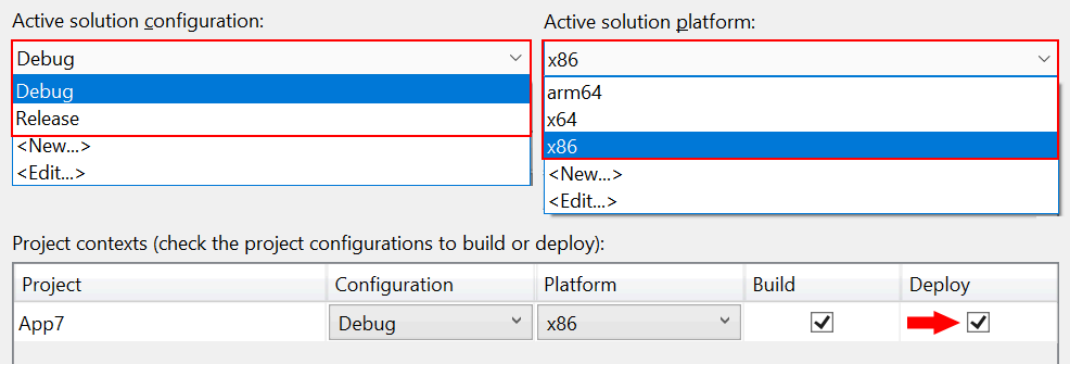


7. Enable deployment for your project in **Configuration Manager**. If you do not follow these steps to enable deployment, you will encounter the following error when you try to run or debug your project on your development computer: "The project needs to be deployed before we can debug. Please enable Deploy in the Configuration Manager".

   a. Select **Build** -> **Configuration Manager**.

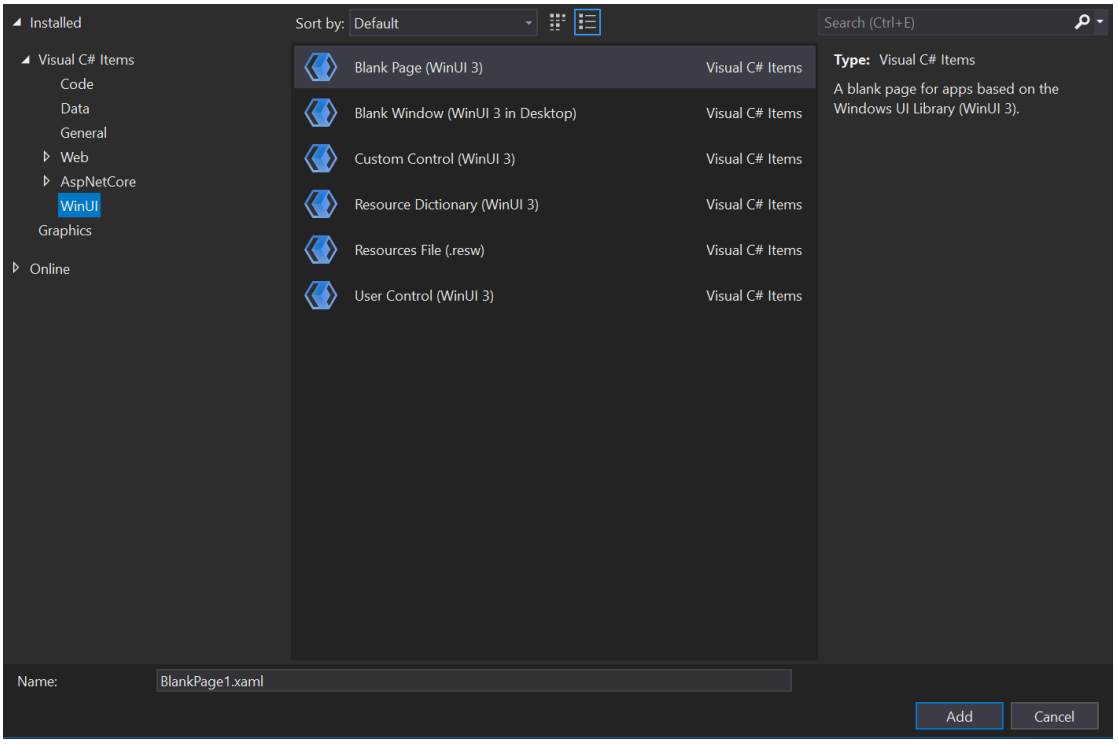
   b. In **Configuration Manager**, click the **Deploy** check box for every combination of configuration and platform (for example, **Debug** and **x86**, **Debug** and **arm64**, **Release** and **x64**, and more).

   > **Note**
   >
   > Be sure to use the **Active solution configuration** and **Active solution platform** drop-downs at the top instead of the **Configuration** and **Platform** drop-downs in the same row as the **Deploy** check box.



8. To add a new item to your app project, right-click the ***Project name*** **(Desktop)** project node in **Solution Explorer** and select **Add** -> **New Item**. In the **Add New Item** dialog box, select the **WinUI** tab, choose the item you want to add,

and then click **Add**. For more details about the available items, see WinUI 3 templates in Visual Studio.



9. Build and run your solution on your development computer to confirm that the app runs without errors.

Localize your WinUI desktop app

To support multiple languages in a WinUI desktop app, and ensure proper localization of your packaged project, add the appropriate resources to the project (see App resources and the Resource Management System) and declare each supported language in the **package.appxmanifest** file of your project. When you build the project, the specified languages are added to the generated app manifest (**AppxManifest.xml**) and the corresponding resources are used.

1. Open the .wapproj's `package.appxmanifest` in a text editor and locate the following section:

```xml
<Resources>
    <Resource Language="x-generate"/>
</Resources>
```

2. Replace the `<Resource Language="x-generate">` with `<Resource />` elements for each of your supported languages. For example, the following markup specifies that "en-US" and "es-ES" localized resources are available:

XML

```
<Resources>
    <Resource Language="en-US"/>
    <Resource Language="es-ES"/>
</Resources>
```

Instructions for WinUI 3 unpackaged desktop apps

> **Note**
>
> WinUI 3 support for unpackaged apps is currently in **preview**, and is not production-ready. You must download the Windows App SDK Preview Extension for Visual Studio to get the project templates and build unpackaged desktop apps with WinUI 3. For a list of the **known issues**, see Windows App SDK 1.0 Preview 3 release notes.

To create a WinUI 3 application without MSIX packaging, choose from one of the following sets of instructions depending on the project language and the version of the Windows App SDK you have installed.

C# with 1.0 Preview 3

To create a WinUI 3 desktop app with C# using Windows App SDK 1.0 Preview 3:

1. Install the Single-project MSIX Packaging Tools.
2. Install the Visual Studio 2019 C# extension or Visual Studio 2022 C# extension, depending on your version of Visual Studio.
3. Install the Windows App SDK runtime and MSIX packages. These are required to run and deploy your app.
4. Create a new app using the "Blank App, Packaged (WinUI 3 in Desktop)" project template. Starting with a packaged app is required to use XAML diagnostics.
5. Add the following property to your project file—either your `.csproj` (C#) or `.vcxproj` (C++) file:

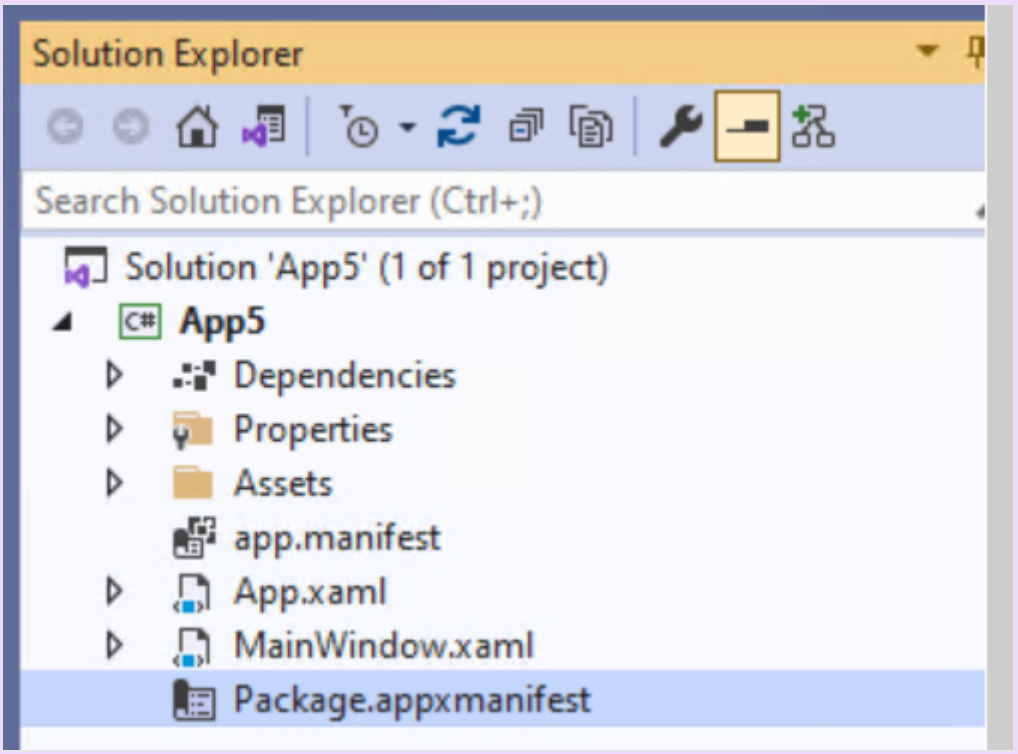
XML

```
<Project ...>
  ...
  <PropertyGroup>
    ...
    <WindowsPackageType>None</WindowsPackageType>
  </PropertyGroup>
  ...
</Project>
```

6. Delete package.appxmanifest from project.

   Otherwise, you will see this error: **Improper project configuration: WindowsPackageType is set to None, but AppxManifest is specified**.

   > ⓘ Note
   >
   > You may need to close the Visual Studio solution to manually delete this file from the filesystem.



7. To debug in Visual Studio, change the debug properties from 'MsixPackage' to 'Project'. Otherwise, you'll see an error: "The project doesn't know how to run the profile ..."

   > ⓘ Note

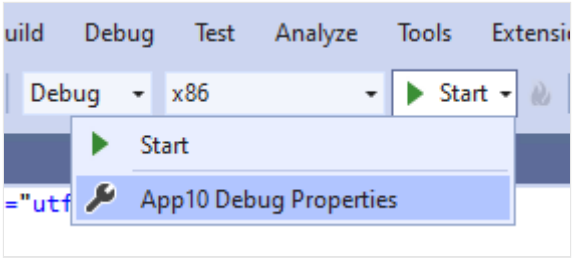
This isn't necessary if you execute the application (`.exe`) from the command line or Windows File explorer.

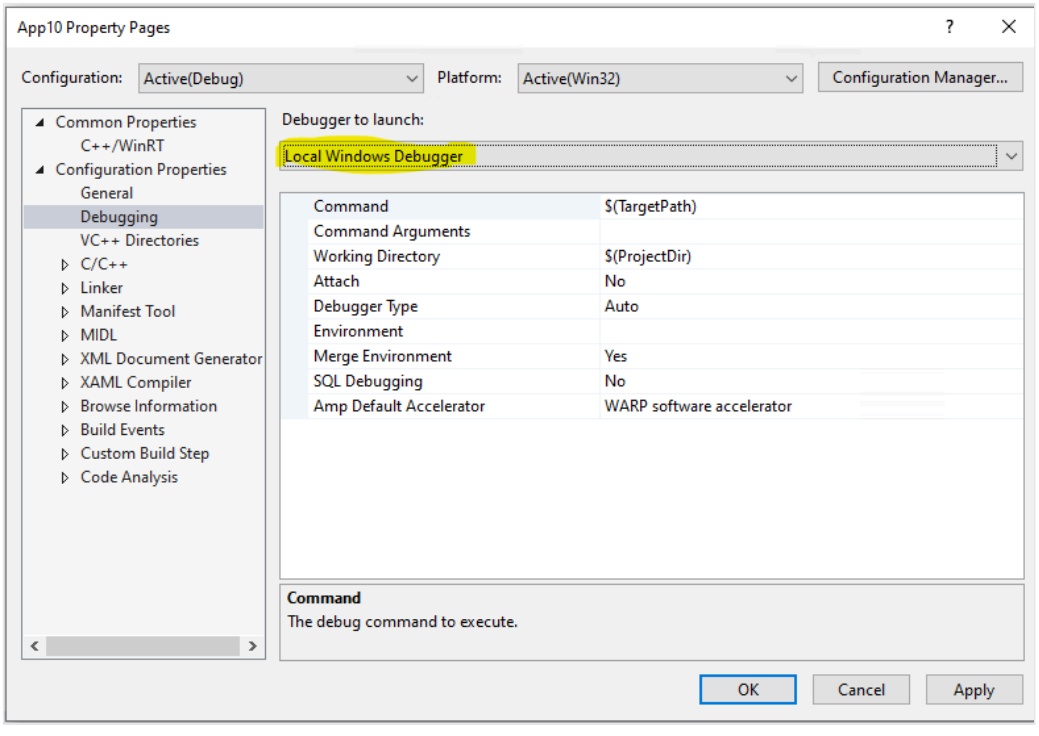
- In **Visual Studio 2022**: Open the launchSettings.json and change the profile with 'MsixPackage' to 'Project'.

```JSON
{
    "profiles": {
        "Preview3": {
            "commandName": "Project"
        }
    }
}
```

- In **Visual Studio 2019 and Visual Studio 2022**: You can use the Visual Studio UI to change the launch settings:

  Open the Debug Properties and change the launch profile to 'Project'





8. If you haven't already done so, **install the Windows App SDK runtime and MSIX packages, which are required to run and deploy your app.**

   Download latest installer & MSIX packages

9. Build and run. For additional deployment information, see the Windows App SDK tutorial for deploying packaged with external location and unpackaged apps (Tutorial: Use the bootstrapper API in an app packaged with external location or unpackaged that uses the Windows App SDK). That tutorial will guide you through using the bootstrapper API (see Use the Windows App SDK runtime for apps packaged with external location or unpackaged) to initialize the Windows App SDK runtime so your app can use Windows App SDK and WinUI 3 APIs.

ASTA to STA threading model

If you're migrating code from an existing UWP app to a new WinUI 3 project that uses the Windows App SDK, be aware that the new project uses the single-threaded apartment (STA) threading model instead of the Application STA (ASTA) threading model used by UWP apps. If your code assumes the non re-entrant behavior of the ASTA threading model, your code may not behave as expected.

Tutorial: Build and deploy an unpackaged app using Preview and Experimental channels of the Windows App SDK

Article • 06/14/2023

Using the Windows App SDK Stable version: You can auto-initialize the Windows App SDK through the `WindowsPackageType` project property when you Create your first WinUI 3 project. You can also follow a tutorial (Tutorial: Use the bootstrapper API in an app packaged with external location or unpackaged that uses the Windows App SDK) in which you configure a packaged with external location or unpackaged app to load the Windows App SDK runtime, and call Windows App SDK APIs.

This article provides a step-by-step tutorial for configuring a packaged with external location or unpackaged app so that it can load the Windows App SDK runtime and call Windows App SDK APIs. This tutorial demonstrates this scenario using a basic Console app project, but the steps apply to any unpackaged desktop app that uses the Windows App SDK.

Before completing this tutorial, we recommend that you review Runtime architecture to learn more about the Framework package dependency your app takes when it uses Reunion, and the additional components required to work in an unpackaged app.

> ⓘ **Note**
>
> The dynamic dependencies and bootstrapper APIs fail when called by an elevated process. As a result, Visual Studio should not be launched elevated. See issue for more details.

Prerequisites

1. Install tools for the Windows App SDK.
2. Ensure that all dependencies for the app are installed (see Windows App SDK deployment guide for framework-dependent apps packaged with external location or unpackaged). The simplest solution is to run the Windows App SDK runtime installer.

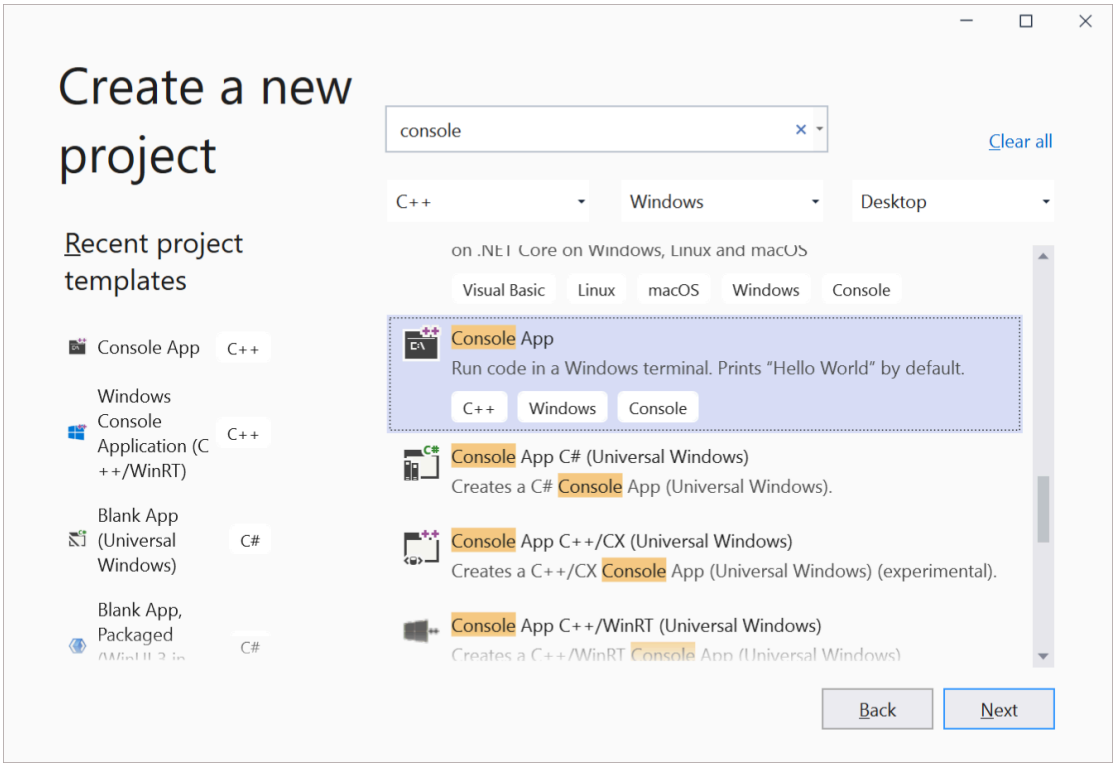
Instructions

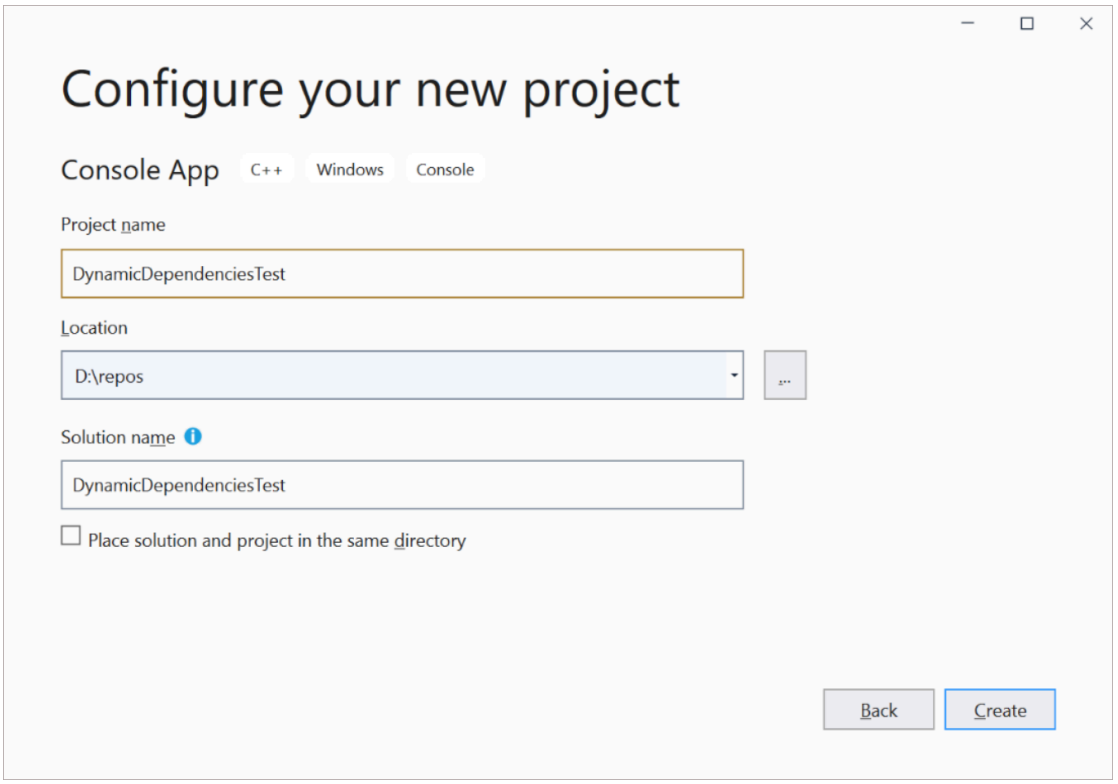
You can choose to follow this tutorial using a C++ project or a C# project.

C++

Follow these instructions to configure a C++ project. Starting in 1.0 Preview 3, you can also configure a C++ project that includes WinUI 3 unpackaged support.

1. In Visual Studio, create a new C++ **Console App** project. Name the project **DynamicDependenciesTest**.





After you create the project, you should have a 'Hello World' C++ console app.

2. Next, install the Windows App SDK NuGet package in your project.
   a. In **Solution Explorer**, right-click the **References** node and choose **Manage Nuget Packages**.
   b. In the **NuGet Package Manager** window, select the **Include prerelease** check box near the top of the window, select the **Browse** tab, and install one of the following packages:

      - To install 1.0 Preview 3 or 1.0 Experimental, search for **Microsoft.WindowsAppSDK**.
      - To install 0.8 Preview, search for **Microsoft.ProjectReunion**.

3. For unpackaged apps, you will need to call the Bootstrapper API to Use the Windows App SDK runtime for apps packaged with external location or unpackaged. This enables you to use Windows App SDK APIs at runtime.

   a. Add the following include files to the top of your **DynamicDependenciesTest.cpp** file. The mddbootstrap.h header is available via the Windows App SDK NuGet package.

```
C++
```

```
#include <windows.h>
#include <MddBootstrap.h>
```

b. Next, add this code at the beginning of your `main` method to call the MddBootstrapInitialize function to initialize the Bootstrapper and handle any errors. This code defines what version of the Windows App SDK the app is dependent upon when initializing the Bootstrapper.

```
C++

// The following code is for 1.0 Preview 3. If using 1.0
Experimental,
// replace with versionTag{ L"experimental1" }. If using version
0.8 Preview,
// replace with majorMinorVersion{ 0x00000008 } and versionTag{
L"preview" }.
const UINT32 majorMinorVersion{ 0x00010000 };
PCWSTR versionTag{ L"preview3" };
const PACKAGE_VERSION minVersion{};

const HRESULT hr{ MddBootstrapInitialize(majorMinorVersion,
versionTag, minVersion) };

// Check the return code for errors. If there is an error,
display the result.
if (FAILED(hr))
{
    wprintf(L"Error 0x%X in MddBootstrapInitialize(0x%08X, %s,
%hu.%hu.%hu.%hu)\n",
        hr, majorMinorVersion, versionTag, minVersion.Major,
minVersion.Minor, minVersion.Build, minVersion.Revision);
    return hr;
}
```

c. Finally, add this code to display the string `Hello World!` and call the MddBootstrapShutdown function to uninitialize the Bootstrapper.

```
C++

std::cout << "Hello World!\n";

// Release the DDLM and clean up.
MddBootstrapShutdown();
```

d. Your final code should look like this.

```
C++

#include <iostream>
#include <windows.h>
#include <MddBootstrap.h>
```

```
int main()
{

    // Take a dependency on Windows App SDK 1.0 Preview 3. If
using 1.0 Experimental,
    // replace with versionTag{ L"experimental1" }. If using
version 0.8 Preview,
    // replace with majorMinorVersion{ 0x00000008 } and
versionTag{ L"preview" }.
    const UINT32 majorMinorVersion{ 0x00010000 };
    PCWSTR versionTag{ L"preview3" };
    const PACKAGE_VERSION minVersion{};

    const HRESULT hr{ MddBootstrapInitialize(majorMinorVersion,
versionTag, minVersion) };

    // Check the return code. If there is a failure, display the
result.
    if (FAILED(hr))
    {
        wprintf(L"Error 0x%X in MddBootstrapInitialize(0x%08X,
%s, %hu.%hu.%hu.%hu)\n",
            hr, majorMinorVersion, versionTag, minVersion.Major,
minVersion.Minor, minVersion.Build, minVersion.Revision);
        return hr;
    }

    std::cout << "Hello World!\n";

    // Release the DDLM and clean up.
    MddBootstrapShutdown();
}
```

4. Press F5 to build and run your app.

Tutorial: Create a simple photo viewer with WinUI 3

Article • 08/19/2024

> **Note**
>
> For info about the benefits of WinUI 3, as well as other app type options, see Overview of framework options.

In this topic we walk through the process of creating a new WinUI 3 project in Visual Studio; and then building a simple app to display photos. We'll use controls, layout panels, and data-binding. And we'll be writing both XAML markup (which is *declarative*) and your choice of either C# or C++ code (which are *imperative*, or *procedural*). Use the language picker above the topic title to choose C# or C++/WinRT.

> **Tip**
>
> The source code in this topic is provided in both C# and C++/WinRT. If you're a C++ developer, then for more details and concepts explaining how the code that we show here works, see the C++/WinRT documentation. Relevant topics there include XAML controls; bind to a C++/WinRT property, XAML items controls; bind to a C++/WinRT collection, and Photo Editor C++/WinRT sample application.

Step 1: Install tools for the Windows App SDK

To set up your development computer, see Get started with WinUI. In that article, you'll also find instructions to create and launch a WinUI 3 project.

> **Important**
>
> You'll find release notes topics along with the Windows App SDK release channels topic. There are release notes for each channel. Be sure to check any *limitations and known issues* in those release notes, since those might affect the results of following along with this tutorial and/or running the app we'll build.

Step 2: Create a new project

In Visual Studio, create your choice of a new C# or C++ project from the **Blank App, Packaged (WinUI 3 in Desktop)** project template. Name the project *SimplePhotos*, and (so that your folder structure will match the one described in this tutorial) uncheck **Place solution and project in the same directory**. You can target the most recent release (not preview) of the client operating system.

Step 3: Copy asset files

The app that we'll be building carries image files around with it in the form of asset files; and those are the photos that it displays. In this section you'll add those assets to your project. But first you'll need to obtain a copy of the files.

1. So clone (or download as a `.zip`) the Windows App SDK samples repo (see WindowsAppSDK-Samples). Having done that, you'll find the asset files that we'll be using in the folder `\WindowsAppSDK-Samples\Samples\PhotoEditor\cs-winui\Assets\Samples` (use this folder for both a C# and a C++/WinRT project). If you want to see those files in the repo online, then you can visit WindowsAppSDK-Samples/Samples/PhotoEditor/cs-winui/Assets/Samples/.

2. In **File Explorer**, select that **Samples** folder, and copy it to the clipboard.

C#

3. Go to **Solution Explorer** in Visual Studio. Right-click the **Assets** folder (it's a child of the project node), and click **Open Folder in File Explorer**. That opens the **Assets** folder in **File Explorer**.

4. Paste (into the **Assets** folder) the **Samples** folder that you just copied.

Step 4: Add a GridView control

Our app needs to display rows and columns of photos. In other words, a grid of images. For a UI like that, the main controls to use are List view and grid view.

1. Open `MainWindow.xaml`. Currently, there's a **Window** element, and within that a **StackPanel** layout panel. Inside the **StackPanel** is a **Button** control, which is hooked up to an event handler method.

The main window of any app represents the view that you see first when you run the app. In the app we'll be building, the main window's job is to load the photos from the **Samples** folder, and to display a tiled view of those images together with various info about them.

2. Replace the **StackPanel** and **Button** markup with the **Grid** layout panel and the **GridView** control shown in the listing below.

```
XAML
```

```
<Window ...>
    <Grid>
        <GridView x:Name="ImageGridView"/>
    </Grid>
</Window>
```

> **Tip**
>
> `x:Name` identifies a XAML element so that you can refer to it elsewhere in the XAML and in the code-behind.

3. **C#**. Open `MainWindow.xaml.cs`, and delete the **myButton_Click** method.

4. **C++/WinRT**. Open `MainWindow.xaml.h` and `MainWindow.xaml.cpp`, and delete the **myButton_Click** method.

You *can* build and run now, but the window will be empty at this stage. For the **GridView** control to show anything, we need to give it a collection of objects to show. We'll make a start on that next.

For background info about some of the types we've just mentioned, see Layout panels and Controls for Windows apps.

Step 5: The ImageFileInfo model

A *model* (in the sense of models, views, and view models) is a class that to some degree represents a real-world object or concept (such as a bank account). It's an *abstraction* of that real-world thing. In this section we'll be adding to our project a new class called **ImageFileInfo**. **ImageFileInfo** will be a model of an image file, such as a photo. This section will take us a step closer to being able to display photos in the app's user interface (UI).

> **Tip**
>
> In preparation for the code example below, let's introduce the term *observable*. A property that can be dynamically bound to a XAML control (so that the UI updates each time the property value changes) is known as an *observable* property. This idea is based on the software design pattern known as the observer pattern. In the app that we build in this tutorial, the properties of our **ImageFileInfo** model won't change. But even so, we'll show how to make **ImageFileInfo** observable, by having it implement the INotifyPropertyChanged interface.

C#

1. Right-click the project node (**SimplePhotos**), and click **Add** > **New Item...**. Under **C# Items** > **Code**, select **Class**. Set the name to *ImageFileInfo.cs*, and click **Add**.

2. Replace the contents of `ImageFileInfo.cs` with the code listing below.

C#

```
using Microsoft.UI.Xaml.Media.Imaging;
using System;
using System.ComponentModel;
using System.Runtime.CompilerServices;
using System.Threading.Tasks;
using Windows.Storage;
using Windows.Storage.FileProperties;
using Windows.Storage.Streams;

namespace SimplePhotos
{
    public class ImageFileInfo : INotifyPropertyChanged
    {
        public ImageFileInfo(ImageProperties properties,
            StorageFile imageFile,
            string name,
            string type)
        {
            ImageProperties = properties;
            ImageName = name;
            ImageFileType = type;
            ImageFile = imageFile;
            var rating = (int)properties.Rating;
            var random = new Random();
            ImageRating = rating == 0 ? random.Next(1, 5) : rating;
        }
```

```
        public StorageFile ImageFile { get; }

        public ImageProperties ImageProperties { get; }

        public async Task<BitmapImage> GetImageSourceAsync()
        {
            using IRandomAccessStream fileStream = await
ImageFile.OpenReadAsync();

            // Create a bitmap to be the image source.
            BitmapImage bitmapImage = new();
            bitmapImage.SetSource(fileStream);

            return bitmapImage;
        }

        public async Task<BitmapImage> GetImageThumbnailAsync()
        {
            StorageItemThumbnail thumbnail =
                await
ImageFile.GetThumbnailAsync(ThumbnailMode.PicturesView);
            // Create a bitmap to be the image source.
            var bitmapImage = new BitmapImage();
            bitmapImage.SetSource(thumbnail);
            thumbnail.Dispose();

            return bitmapImage;
        }

        public string ImageName { get; }

        public string ImageFileType { get; }

        public string ImageDimensions => $"{ImageProperties.Width}
x {ImageProperties.Height}";

        public string ImageTitle
        {
            get => string.IsNullOrEmpty(ImageProperties.Title) ?
ImageName : ImageProperties.Title;
            set
            {
                if (ImageProperties.Title != value)
                {
                    ImageProperties.Title = value;
                    _ = ImageProperties.SavePropertiesAsync();
                    OnPropertyChanged();
                }
            }
        }

        public int ImageRating
        {
            get => (int)ImageProperties.Rating;
            set
```

```
            {
                if (ImageProperties.Rating != value)
                {
                    ImageProperties.Rating = (uint)value;
                    _ = ImageProperties.SavePropertiesAsync();
                    OnPropertyChanged();
                }
            }
        }

        public event PropertyChangedEventHandler PropertyChanged;

        protected void OnPropertyChanged([CallerMemberName] string
propertyName = null) =>
            PropertyChanged?.Invoke(this, new
PropertyChangedEventArgs(propertyName));
    }
}
```

3. Save and close the `ImageFileInfo.cs` file.

Step 6: Define and populate a property for a collection of images

In this section we'll add a new property to the **MainWindow** class. The property (named **Images**) will be a collection class that contains the images that we want to display.

C#

1. Define the property like this, in `MainWindow.xaml.cs`:

```
C#

...
using System.Collections.ObjectModel;
...
namespace SimplePhotos
{
    public sealed partial class MainWindow : Window
    {
        public ObservableCollection<ImageFileInfo> Images { get; }
=
            new ObservableCollection<ImageFileInfo>();
        ...
```

```
    }
}
```

2. The code to populate the new collection property with images is shown in the **GetItemsAsync** and **LoadImageInfoAsync** methods below. Paste the `using` directives, and the two method implementations, into `MainWindow.xaml.cs`, too. These methods are members of the **MainWindow** class, so paste them inside there just as you did with the **Images** property above.

C#

```
...
using System.Threading.Tasks;
using Windows.ApplicationModel;
using Windows.Storage;
using Windows.Storage.Search;
...
private async Task GetItemsAsync()
{
    StorageFolder appInstalledFolder =
Package.Current.InstalledLocation;
    StorageFolder picturesFolder = await
appInstalledFolder.GetFolderAsync("Assets\\Samples");

    var result = picturesFolder.CreateFileQueryWithOptions(new
QueryOptions());

    IReadOnlyList<StorageFile> imageFiles = await
result.GetFilesAsync();
    foreach (StorageFile file in imageFiles)
    {
        Images.Add(await LoadImageInfoAsync(file));
    }

    ImageGridView.ItemsSource = Images;
}

public async static Task<ImageFileInfo>
LoadImageInfoAsync(StorageFile file)
{
    var properties = await
file.Properties.GetImagePropertiesAsync();
    ImageFileInfo info = new(properties,
                             file, file.DisplayName,
file.DisplayType);

    return info;
}
```

3. The last thing we need to do in this section is to update the constructor of **MainWindow** to call **GetItemsAsync**.

```
C#

public MainWindow()
{
    ...
    GetItemsAsync();
}
```

You can build and run now if you like (to confirm you've followed the steps ok), but there's not much to see in the window at this stage. That's because what we've done so far is to ask the **GridView** to render a collection of objects of type **ImageFileInfo**; and the **GridView** doesn't quite know how to do that yet.

Remember that the **Images** property is an observable collection of **ImageFileInfo** objects. And the last line of **GetItemsAsync** tells the **GridView** (which is named *ImageGridView*) that the source of its items (**ItemsSource**) is the **Images** property. And the job of the **GridView** is then to display those items.

But we haven't yet told the **GridView** anything about the **ImageFileInfo** class. So the best it can do so far is to display the **ToString** value of each **ImageFileInfo** object in the collection. And by default, that's just the type's name. In the next section we'll create a data template to define how we want an **ImageFileInfo** object to be displayed.

> **Tip**
>
> I used the term *observable collection* above. In the app that we build in this tutorial, the number of images doesn't change (and as we've said, neither do the values of the properties of each image, either). But it's still convenient, and a good practice, to use data-binding to initially connect the UI to the data. So that's what we'll do.

Step 7: Add a data template

To begin with, let's use a sketch-like placeholder data template. That will serve until we're done exploring some layout options. After that we can update the data template to show the actual photos.

> **Tip**

That's actually a very practical thing to do. It's been found that if a UI looks like a sketch (in other words, low-fidelity), then people are more willing to suggest and/or test out quick ideas with it—sometimes involving quite substantial changes. That's because we guess (correctly) that such changes will be cheap to try.

On the other hand, the more finished a UI looks (the higher fidelity it has), the more we guess (again, correctly) that a lot of work has gone into the current look of it. And that makes us less inclined to suggest, or to try out, new ideas.

1. Open `MainWindow.xaml`, and change the contents of the **Window** so that they look like this markup:

   XAML

   ```
   <Window ...>
       <Grid>
           <Grid.Resources>
               <DataTemplate x:Key="ImageGridView_ItemTemplate">
                   <Grid/>
               </DataTemplate>
           </Grid.Resources>
           <GridView x:Name="ImageGridView"
                     ItemTemplate="{StaticResource
   ImageGridView_ItemTemplate}">
           </GridView>
       </Grid>
   </Window>
   ```

   To the layout root, we've added a simple **DataTemplate** resource, and given it a key of `ImageGridView_ItemTemplate`. And we've used that same key to set the **ItemTemplate** of the **GridView**. Items controls such as **GridView** have an **ItemTemplate** property (just like they have the **ItemsSource** property that we saw earlier). An item template is a data template; and it's used for displaying each item in the collection.

   For more info, see Item containers and templates.

2. Now we can take a few edit passes over the data template—adding to, and editing, the elements inside it to make it more interesting and useful. We'll give the root **Grid** a height and a width of 300, and a margin of 8. Then we'll add two row definitions, and set the height of the second row definition to **Auto**.

   XAML

   ```
   <DataTemplate x:Key="ImageGridView_ItemTemplate">
       <Grid Height="300"
   ```

```
          Width="300"
          Margin="8">
        <Grid.RowDefinitions>
            <RowDefinition />
            <RowDefinition Height="Auto" />
        </Grid.RowDefinitions>
    </Grid>
</DataTemplate>
```

For more info, see Alignment, margin, padding.

3. We want the data template to display each photo's image, name, file type, dimensions, and rating. So we'll be adding, respectively, an **Image** control, some **TextBlock** controls, and a **RatingControl** control. We'll lay out the text inside **StackPanel** layout panels. The **Image** will, initially, display the project's sketch-like Microsoft Store logo as a placeholder.

4. After all those edits, here's how the data template looks:

XAML

```
<DataTemplate x:Key="ImageGridView_ItemTemplate">
    <Grid Height="300"
          Width="300"
          Margin="8">
        <Grid.RowDefinitions>
            <RowDefinition />
            <RowDefinition Height="Auto" />
        </Grid.RowDefinitions>

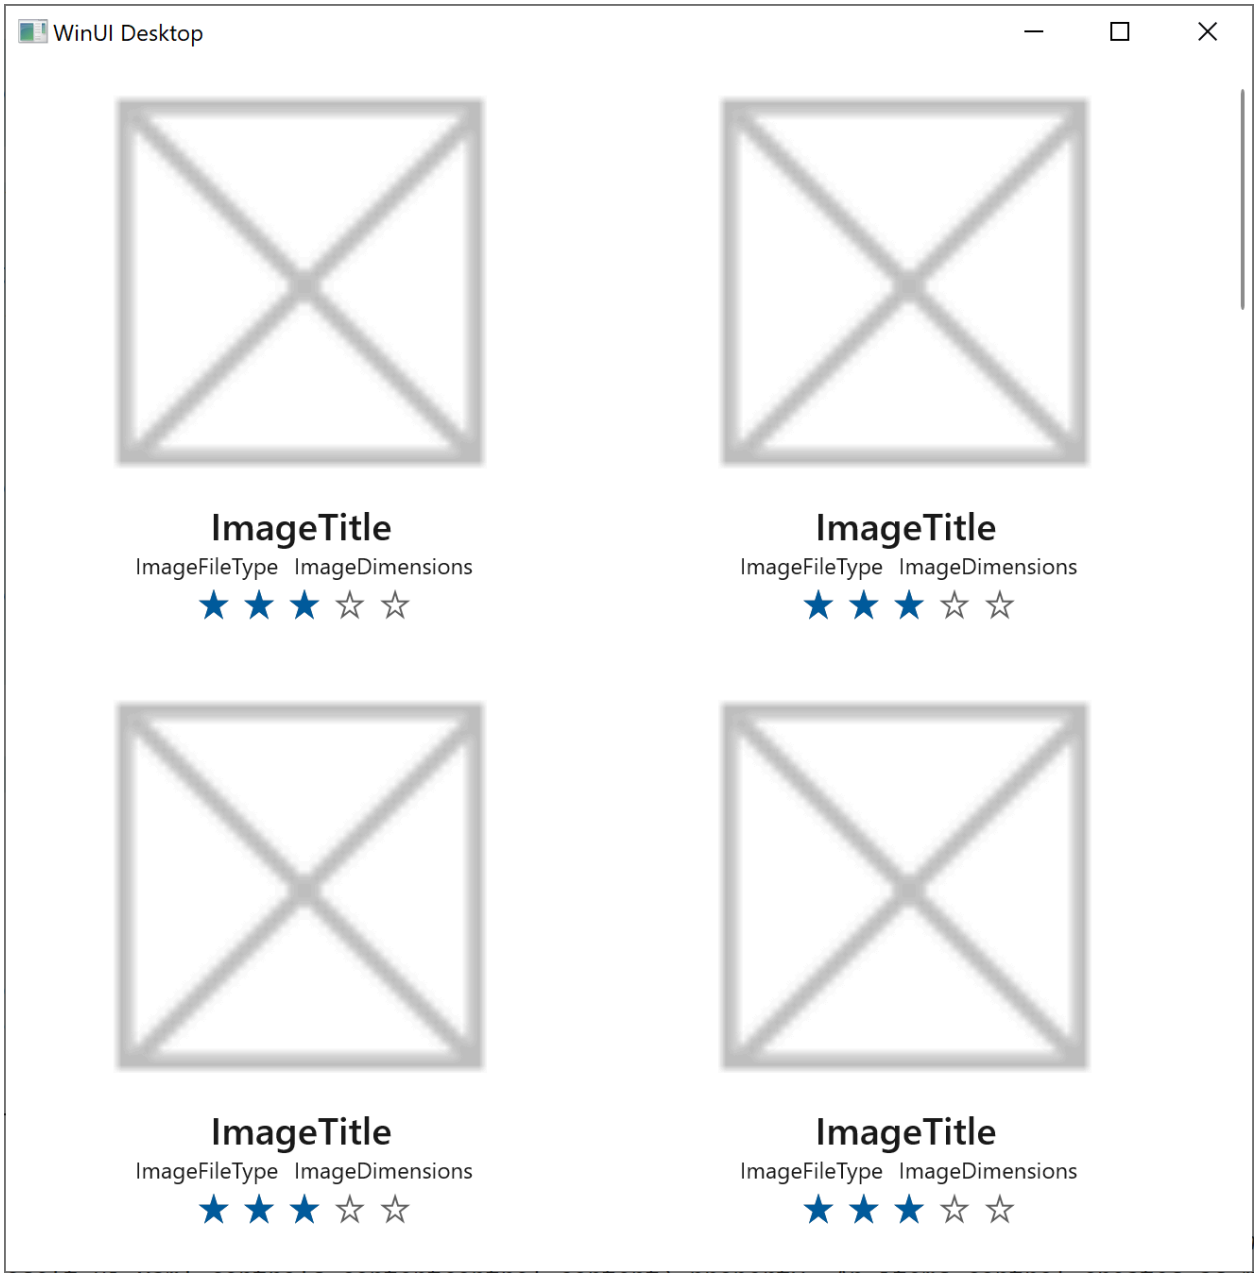
        <Image x:Name="ItemImage"
               Source="Assets/StoreLogo.png"
               Stretch="Uniform" />

        <StackPanel Orientation="Vertical"
                    Grid.Row="1">
            <TextBlock Text="ImageTitle"
                       HorizontalAlignment="Center"
                       Style="{StaticResource SubtitleTextBlockStyle}"
/>
            <StackPanel Orientation="Horizontal"
                        HorizontalAlignment="Center">
                <TextBlock Text="ImageFileType"
                           HorizontalAlignment="Center"
                           Style="{StaticResource
CaptionTextBlockStyle}" />
                <TextBlock Text="ImageDimensions"
                           HorizontalAlignment="Center"
                           Style="{StaticResource
CaptionTextBlockStyle}"
                           Margin="8,0,0,0" />
```

```
            </StackPanel>

            <RatingControl Value="3" IsReadOnly="True"/>
        </StackPanel>
    </Grid>
</DataTemplate>
```

Build the project now, and run the app to see the **GridView** control with the item template that you just created. Next, we'll take a look at how the items are laid out. We'll change some brushes, and we'll add space between the items.



Step 8: Edit the item container's style

Another concept related to items controls such as **GridView** is the *item container*. An item container is a *content control* that displays an item as the value of its Content

property. An items control creates as many item containers as it needs in order to display the items that are visible on the screen at any time.

Being a control, an item container has a style and a control template. Its style and control template determine how the item container looks in its various states (such as selection, pointer over, and focus). And, as we've seen, the item template (which is a data template) determines how the item itself looks.

For **GridView**, the type of its item containers is **GridViewItem**.

So in this section we'll focus on designing the item container's style. And for that we'll be creating a **Style** resource for **GridViewItem**, and then setting that as the **ItemContainerStyle** of the ***GridView**. In the style, we'll set the **Background** and **Margin** properties of the item container to give it a gray background and a bit of a margin around the outside of it.

1. In `MainWindow.xaml`, add a new **Style** resource to the same **Grid.Resources** XML element that we put the data template into.

   XAML

   ```
   <Grid>
       <Grid.Resources>
       ...
           <Style x:Key="ImageGridView_ItemContainerStyle"
               TargetType="GridViewItem">
               <Setter Property="Background" Value="Gray"/>
               <Setter Property="Margin" Value="8"/>
           </Style>
       </Grid.Resources>
   ```

2. Next, we use the `ImageGridView_ItemContainerStyle` key to set the **ItemContainerStyle** of the **GridView**.

   XAML

   ```
   <GridView x:Name="ImageGridView"
           ...
           ItemContainerStyle="{StaticResource
   ImageGridView_ItemContainerStyle}">
   </GridView>
   ```

Build and run the app, and see how it looks now. As you resize the window, the **GridView** control takes care of rearranging the items to best fit into the space. At some widths, there's a lot of space on the right-hand side of the app window. It would look better if the **GridView**, and/or its contents, were centered. So we'll take care of that next.

> **Tip**
>
> If you want to experiment, try setting the **Background** and **Margin** setters to different values to see what effect that has.

Step 9: Experimenting with layout

You might be wondering whether it's best to center the **GridView** itself, or to center its contents. Let's try centering the **GridView** first.

1. To make it easy to see exactly where the **GridView** is in the Window—and what happens as we experiment with layout—we'll set its **Background** property to red.

   XAML

   ```
   <GridView x:Name="ImageGridView"
             ...
             Background="Red">
   </GridView>
   ```

2. And now we'll set its **HorizontalAlignment** property to *Center*.

   XAML

   ```
   <GridView x:Name="ImageGridView"
             ...
             HorizontalAlignment="Center">
   </GridView>
   ```

   Also see Alignment, margin, padding.

Build and run now, and experiment with adjusting the width of the window. You can see that there's an equal amount of empty space on either side of the **GridView**'s red background. So we have achieved the goal of centering the images. But it's now clearer than before that the scroll bar belongs to the **GridView**, and not to the window. So we need to change the **GridView** back to filling the window. We've demonstrated that (instead of centering the **GridView** in the window) we need to center the images in the **GridView**.

3. So now delete the **HorizontalAlignment** attribute that you added in the previous step.

Step 10: Edit the items panel template

Items controls lay out their item containers inside what's known as an *items panel*. We can define what kind of panel is used, and set properties on that panel, by editing the **GridView**'s *items panel template*. So that's what we'll do in this section.

1. In `MainWindow.xaml`, add an **ItemsPanelTemplate** resource to our resource dictionary. The items panel is of type **ItemsWrapGrid**, and we're setting its **HorizontalAlignment** property to **Center**.

   XAML

   ```
   <Grid>
       <Grid.Resources>
       ...
           <ItemsPanelTemplate x:Key="ImageGridView_ItemsPanelTemplate">
               <ItemsWrapGrid Orientation="Horizontal"
                              HorizontalAlignment="Center"/>
           </ItemsPanelTemplate>
       </Grid.Resources>
   ```

2. Next, we use the `ImageGridView_ItemsPanelTemplate` key to set the **ItemsPanel** of the **GridView**.

   XAML

   ```
   <GridView x:Name="ImageGridView"
           ...
           ItemsPanel="{StaticResource ImageGridView_ItemsPanelTemplate}">
   </GridView>
   ```

When you build and run this time, and experiment with adjusting the width of the window, there's an equal amount of the **GridView**'s red background on either side of the images. And because the **GridView** fills the window, the scroll bar aligns nicely with the edge of the window, where users might expect it to be.

3. Now that we're done experiment with layout, remove `Background="Red"` from the **GridView**.

Step 11: Replace the placeholder image with a photo

Now it's time to move our sketch to a higher level of fidelity; and that means replacing the placeholder image with the real ones, and replacing the "lorem ipsum"-style

placeholder text with real data. Let's take care of the images first.

> **ⓘ Important**
>
> The technique we'll use to display the photos in the `Assets\Samples` folder involves updating the **GridView**'s items progressively. Specifically, that's the code in the **ImageGridView_ContainerContentChanging** and **ShowImage** methods in the code example below, including use of the **ContainerContentChangingEventArgs.InRecycleQueue** and **ContainerContentChangingEventArgs.Phase** properties. For more info, see ListView and GridView UI optimization. But in a nutshell, the **GridView** will let us know (by way of an event) when one of its item containers is ready to display its item. And then we'll keep track of which phase of its update lifecycle the item container is in so that we can determine when it's ready to display photo data.

C#

1. In `MainWindow.xaml.cs`, add a new method to **MainWindow** named **ImageGridView_ContainerContentChanging**. This is an event-handling method, and the event it handles is ContainerContentChanging. We also need to provide the implementation of the **ShowImage** method that **ImageGridView_ContainerContentChanging** depends on. Paste the `using` directive and the two method implementations into `MainWindow.xaml.cs`:

   C#

   ```
   ...
   using Microsoft.UI.Xaml.Controls;
   ...
   private void ImageGridView_ContainerContentChanging(
       ListViewBase sender,
       ContainerContentChangingEventArgs args)
   {
       if (args.InRecycleQueue)
       {
           var templateRoot = args.ItemContainer.ContentTemplateRoot
   as Grid;
           var image = templateRoot.FindName("ItemImage") as Image;
           image.Source = null;
       }

       if (args.Phase == 0)
       {
           args.RegisterUpdateCallback(ShowImage);
           args.Handled = true;
   ```

```
    }
}

private async void ShowImage(ListViewBase sender,
ContainerContentChangingEventArgs args)
{
    if (args.Phase == 1)
    {
        // It's phase 1, so show this item's image.
        var templateRoot = args.ItemContainer.ContentTemplateRoot
as Grid;
        var image = templateRoot.FindName("ItemImage") as Image;
        var item = args.Item as ImageFileInfo;
        image.Source = await item.GetImageThumbnailAsync();
    }
}
```

2. Then, in `MainWindow.xaml`, register the **ImageGridView_ContainerContentChanging** event-handler with the **GridView**'s **ContainerContentChanging** event.

XAML

```
<GridView x:Name="ImageGridView"
        ...

ContainerContentChanging="ImageGridView_ContainerContentChanging">
</GridView>
```

Step 12: Replace the placeholder text with real data

In this section we'll use one-time data-bindings. A one-time binding is great for data that doesn't change at run-time. And that means that one-time bindings are high-performance and easy to create.

1. In `MainWindow.xaml`, find the *ImageGridView_ItemTemplate* data template resource. We're going to tell the data template that its job is to be a template for the **ImageFileInfo** class, which you'll recall is the type of the items that our **GridView** is displaying.

2. To do that, add an `x:DataType` value to the template, like this:

XAML

```
<DataTemplate x:Key="ImageGridView_ItemTemplate"
              x:DataType="local:ImageFileInfo">
    ...
```

If you're unfamiliar with the `local:` syntax shown above (or with the `xmlns:local` syntax already in the opening **Window** tag), then see XAML namespaces and namespace mapping.

Now that we've set an `x:DataType`, we can use `x:Bind` data-binding expressions in the data template to bind to properties of the data type we specified (**ImageFileInfo**, in this case).

3. In the data template, find the first **TextBlock** element (the one with its **Text** currently set to *ImageTitle*). Replace its **Text** value as shown below.

> **Tip**
>
> You can either copy and paste the markup below, or you can use IntelliSense in Visual Studio. To do that, select the current value that's inside the quotation marks, and type `{`. IntelliSense automatically adds the closing brace, and displays a code-completion list. You *could* scroll down to `x:Bind`, and double-click it. But it might be more efficient to type `x:` (note how `x:Bind` is then filtered to the top of the completion list), and press the TAB key. Now press the SPACE key, and type `ImageT` (as much of the property name `ImageTitle` as necessary to get it to the top of the completion list), and TAB.

XAML

```
<TextBlock Text="{x:Bind ImageTitle}"
    ... />
```

An `x:Bind` expression links the value of a UI property with the value of a **data-object** property. Of course, that depends on first setting `x:DataType` to the type of that **data-object** so that the tooling and the runtime know what properties are available to bind to.

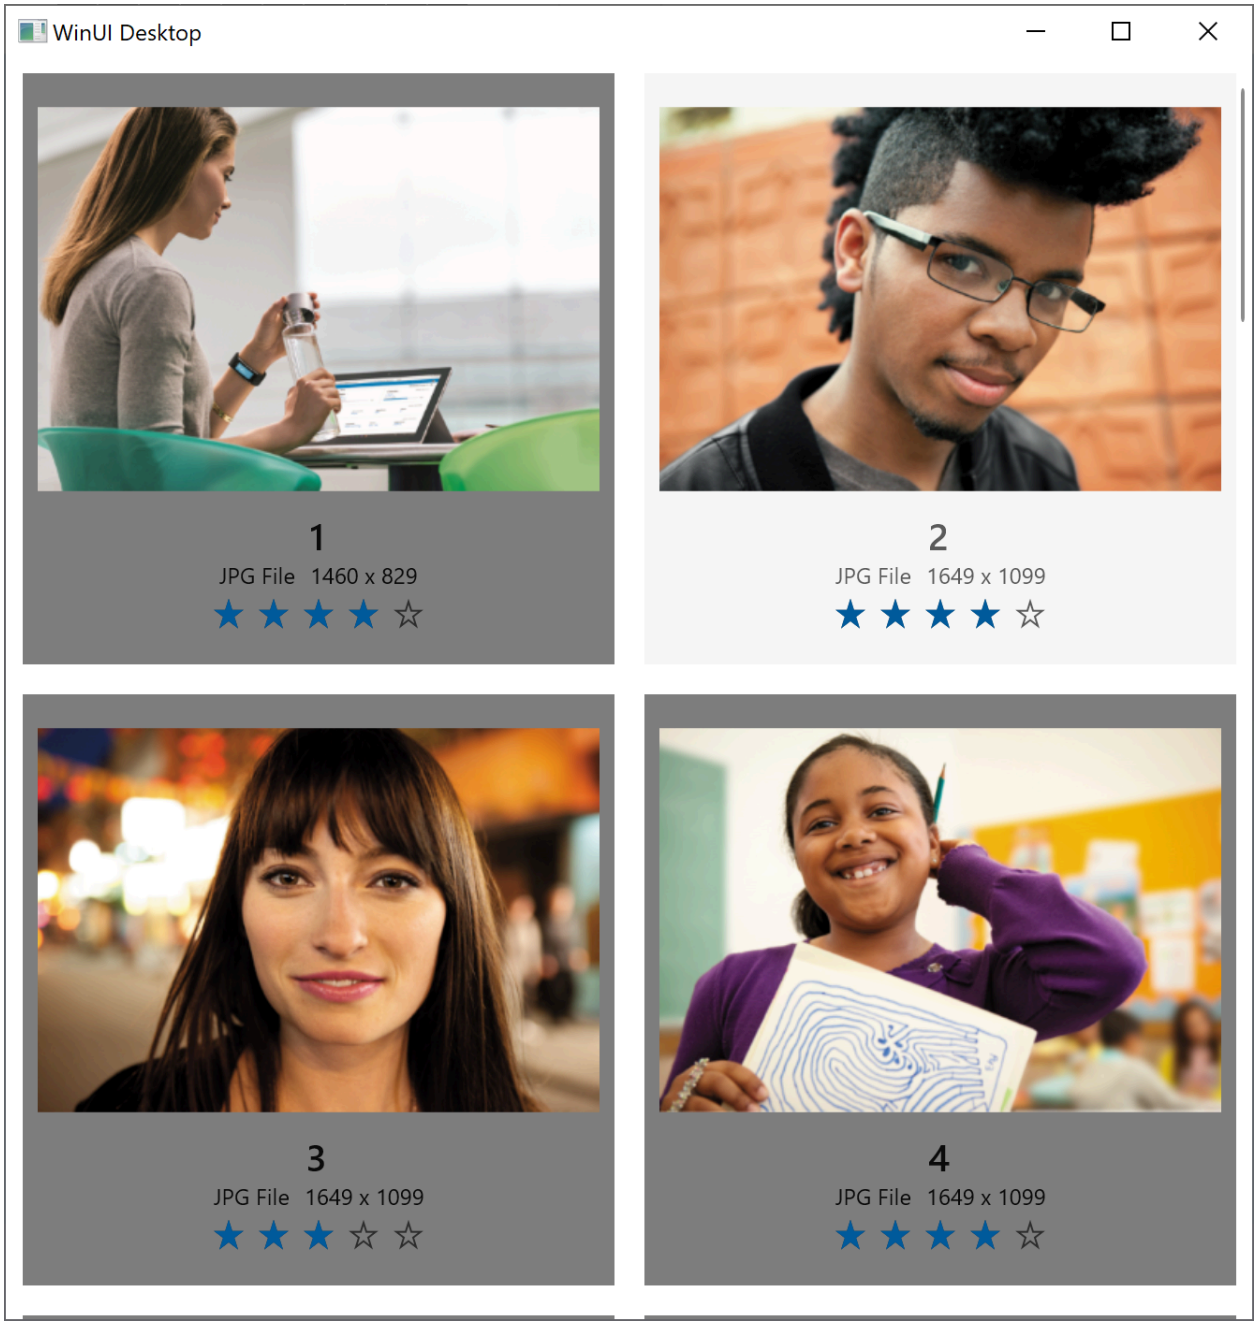
For more info, see {x:Bind} markup extension and Data binding in depth.

4. In the same way, replace the values of the other **TextBlock**s and the **RatingControl**. Here's the result:

XAML

```
<TextBlock Text="{x:Bind ImageTitle}" ... />
<StackPanel ... >
    <TextBlock Text="{x:Bind ImageFileType}" ... />
    <TextBlock Text="{x:Bind ImageDimensions}" ... />
</StackPanel>
<RatingControl Value="{x:Bind ImageRating}" ... />
```

If you build and run the app now, instead of placeholders you'll see real photos, and real text (and other data). Visually and functionally, this simple little app is now complete. But as a coda, let's do one last little bit of data binding.



Step 13: Bind the GridView to the Images collection (C# only)

> **Important**
>
> Perform this last step only if you created a C# project.

> **Tip**
>
> You'll find that there are some things (usually related to dynamically-generated UI) that you can't do in XAML markup. But in general if you *can* do something in markup, then that's preferable. It gives a slightly cleaner separation between the *view* that the XAML markup represents and the *model* (or *view model*) that the imperative code represents. And that tends to improve workflow in tooling and between team members.

We're currently using imperative code to associate the **GridView**'s ItemsSource) property with **MainWindow**'s **Images** property. But we can do that in markup instead.

1. In the **MainWindow** class, delete (or comment-out) the last line of **GetItemsAsync**, which sets the **ItemsSource** of `ImageGridView` to the value of the **Images** property.

2. And then in `MainWindow.xaml`, find the **GridView** named *ImageGridView*, and add an **ItemsSource** attribute like this. You can use IntelliSense to make this change if you like.

   XAML

   ```
   <GridView x:Name="ImageGridView"
             ...
             ItemsSource="{x:Bind Images}"
   ```

The **Images** property value doesn't change at run-time for this particular app. But because **Images** is of type `ObservableCollection<T>`, the *contents* of the collection can change (that is, elements can be added or deleted), and the binding will automatically notice the changes and update the UI.

Conclusion

In this tutorial we walked through the process of using Visual Studio to build a simple WinUI 3 app that displays photos. Hopefully this tutorial has given you experience working in a WinUI 3 app with controls, layout panels, data-binding, and GridView UI optimization.

Tutorial: Build a simple photo viewer that targets multiple platforms

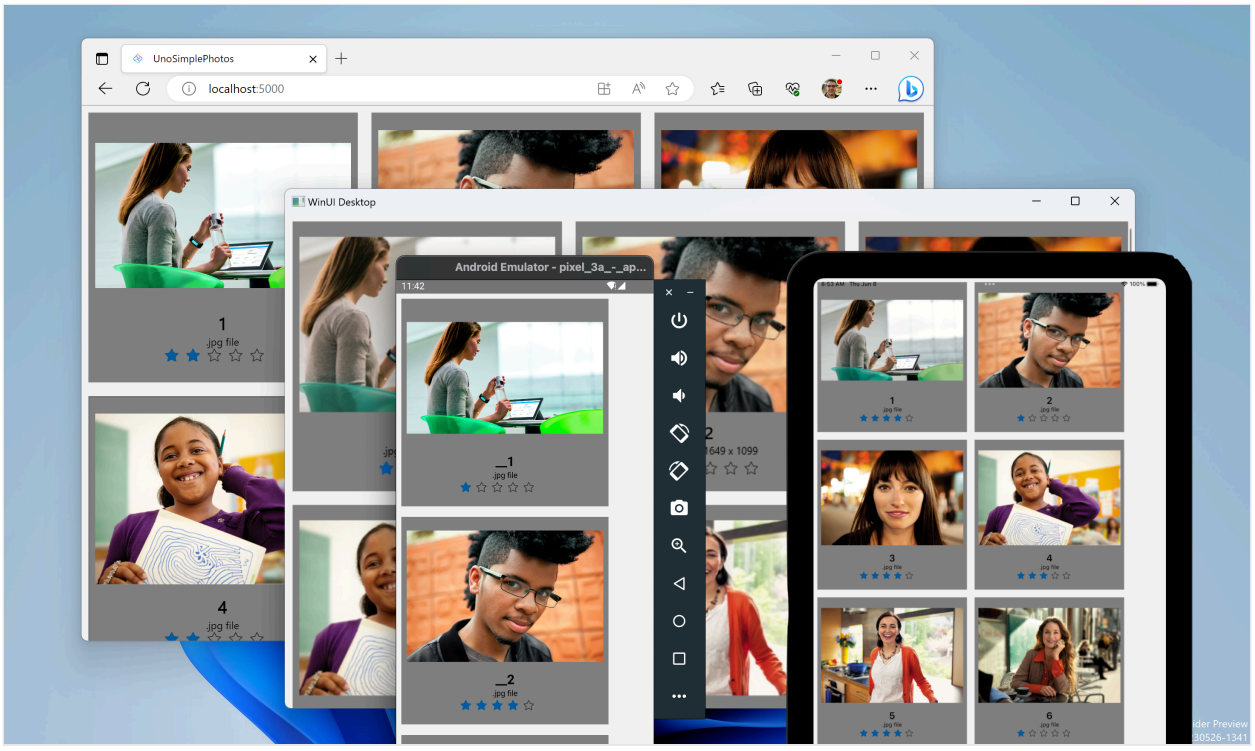
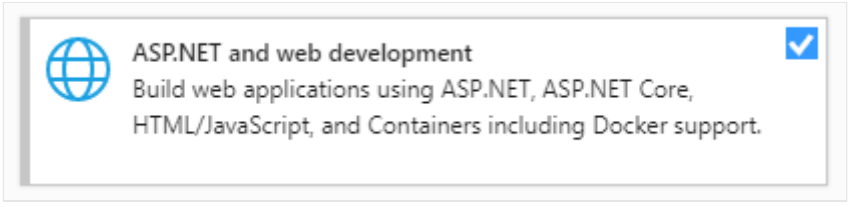
Article • 08/19/2024

After you've created a starter simple photo viewer WinUI 3 app, you might be wondering how to reach more users without having to rewrite your app. This tutorial uses Uno Platform to expand the reach of your existing C# WinUI 3 application enabling reuse of the business logic and UI layer across native mobile, web, and desktop. With only minimal changes to the simple photo viewer app, we can run a pixel-perfect copy of the app ported to these platforms.

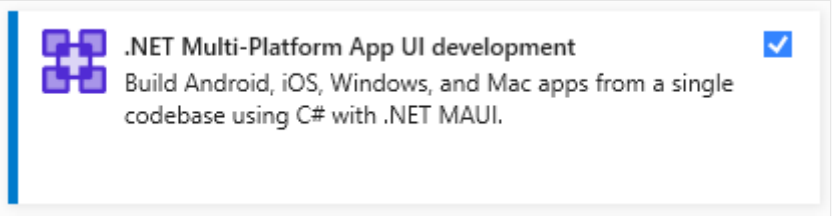


Prerequisites

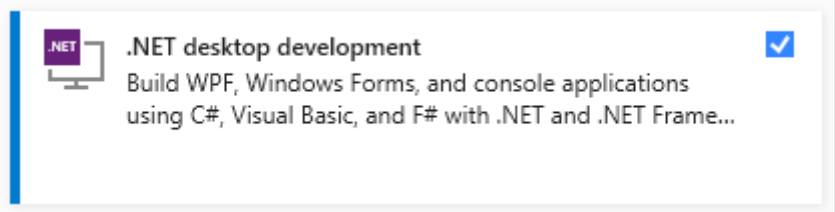
- Visual Studio 2022 17.4 or later
- Set up your development computer (see Get started with WinUI)
- ASP.NET and web development workload (for WebAssembly development)



- .NET Multi-platform App UI development installed (for iOS, Android, Mac Catalyst development)



- .NET desktop development installed (for Gtk, Wpf, and Linux Framebuffer development)



Finalize your environment

1. Open a command-line prompt, Windows Terminal if you have it installed, or else Command Prompt or Windows Powershell from the Start Menu.
2. Install or update the `uno-check` tool:
    - Use the following command:

      .NET CLI

      ```
      dotnet tool install -g uno.check
      ```

    - To update the tool, if you already have previously installed an older version:

      .NET CLI

      ```
      dotnet tool update -g uno.check
      ```

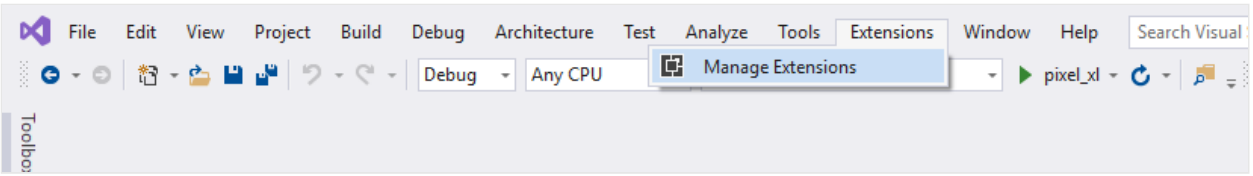
3. Run the tool with the following command:

   ```
   uno-check
   ```

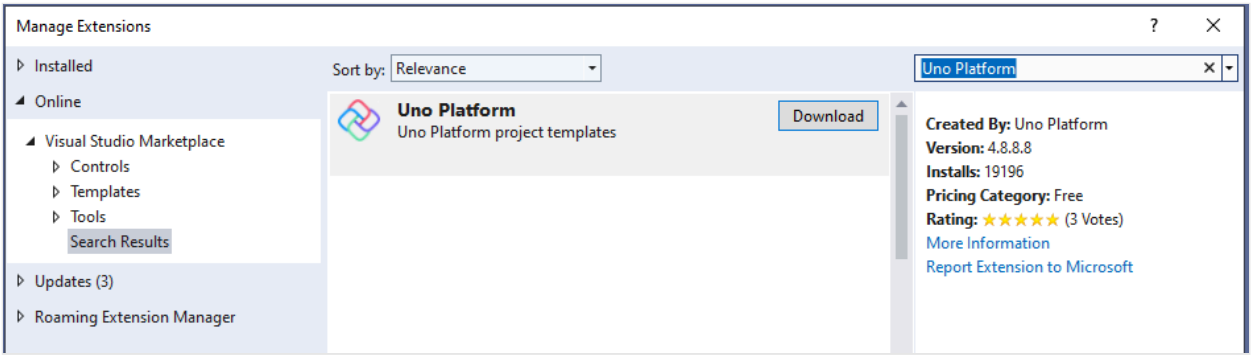
4. Follow the instructions indicated by the tool. Because it needs to modify your system, you may be prompted for elevated permissions.

Install the Uno Platform solution templates

Launch Visual Studio, then click `Continue without code`. Click `Extensions` -> `Manage Extensions` from the Menu Bar.



In the Extension Manager expand the **Online** node and search for `Uno`, install the `Uno Platform` extension, or download and install it from the Visual Studio Marketplace, then restart Visual Studio.

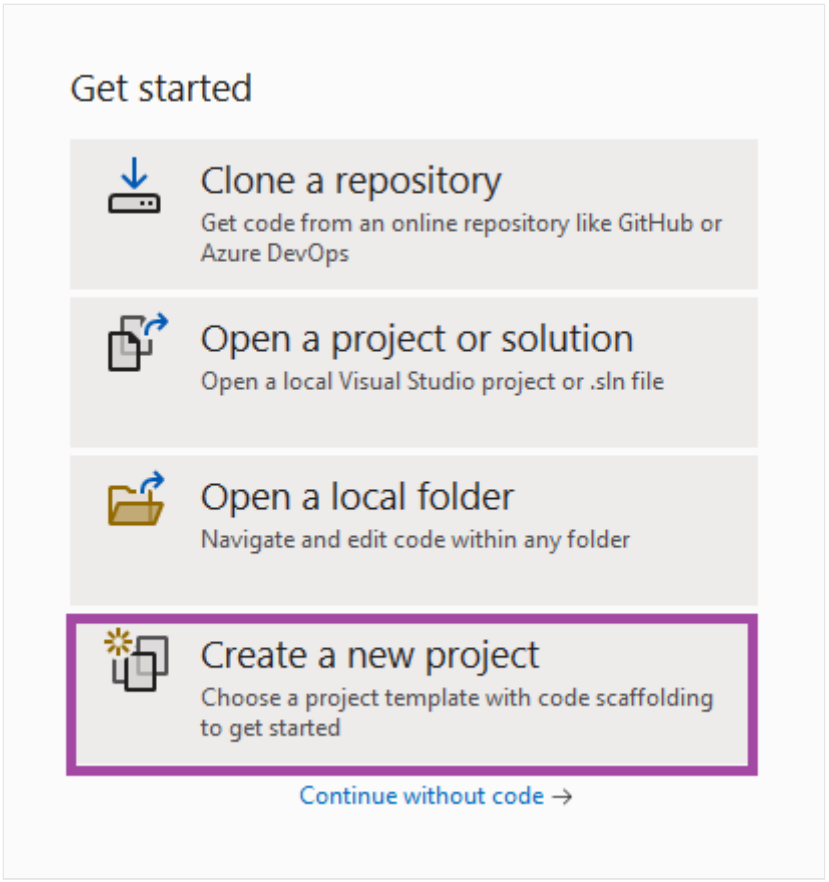


Create an application

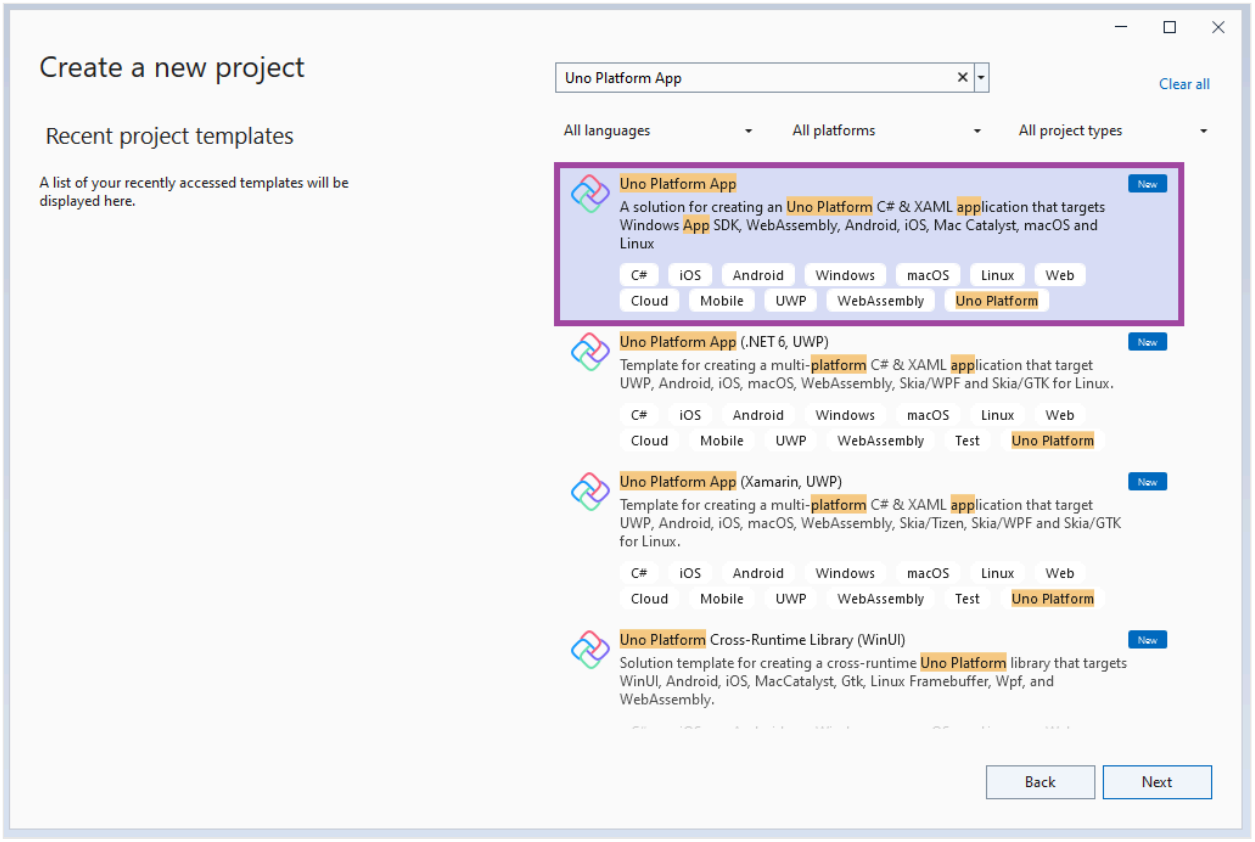
Now that we're ready to create a multi-platform application, the approach we'll take is to create a new Uno Platform application. We'll copy code from the previous tutorial's **SimplePhotos** WinUI 3 project into our multi-platform project. This is possible because Uno Platform lets you reuse your existing codebase. For features dependent on OS APIs provided by each platform, you can easily make them work over time. This approach is especially useful if you have an existing application that you want to port to other platforms.

Soon enough, you will be able to reap the benefits of this approach, as you can target more platforms with a familiar XAML flavor and the codebase you already have.

Open Visual Studio and create a new project via `File` > `New` > `Project`:

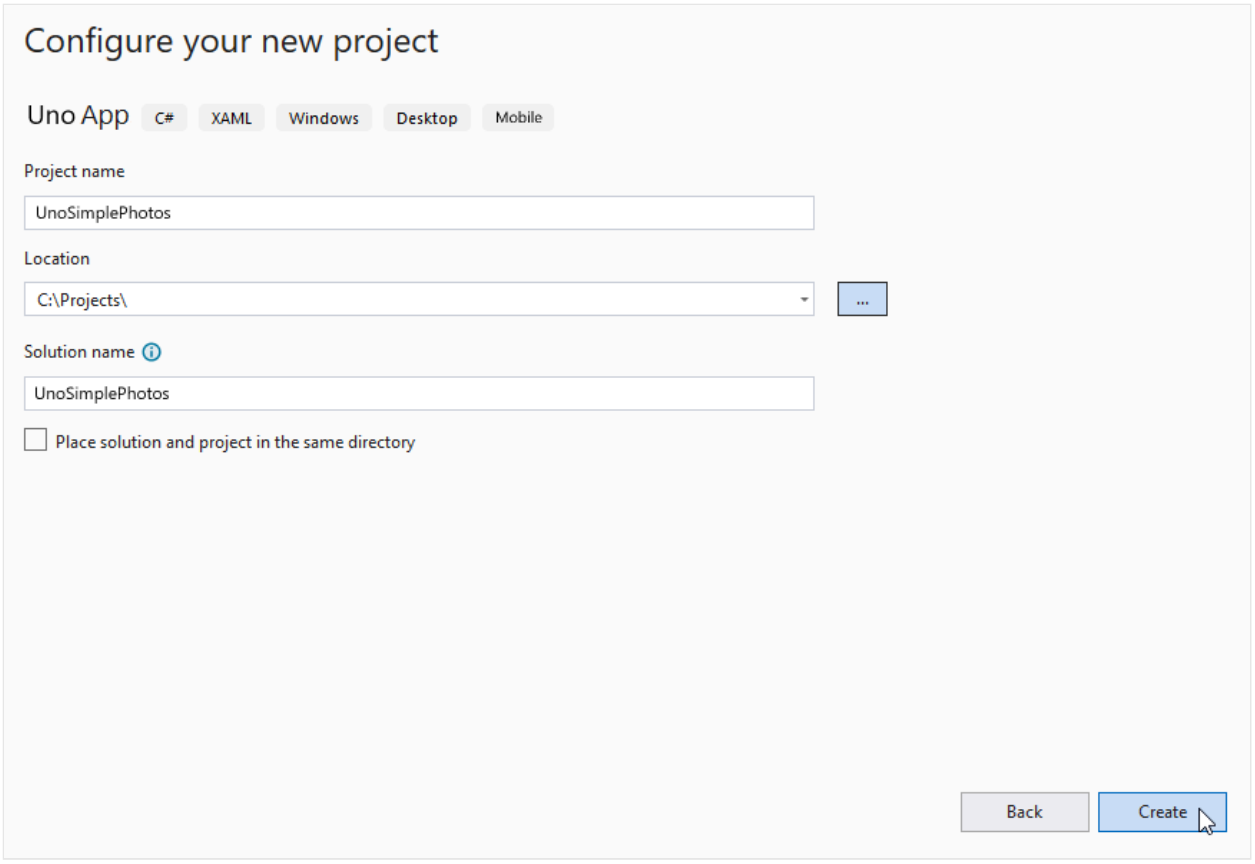


Search for Uno and select the Uno Platform App project template:



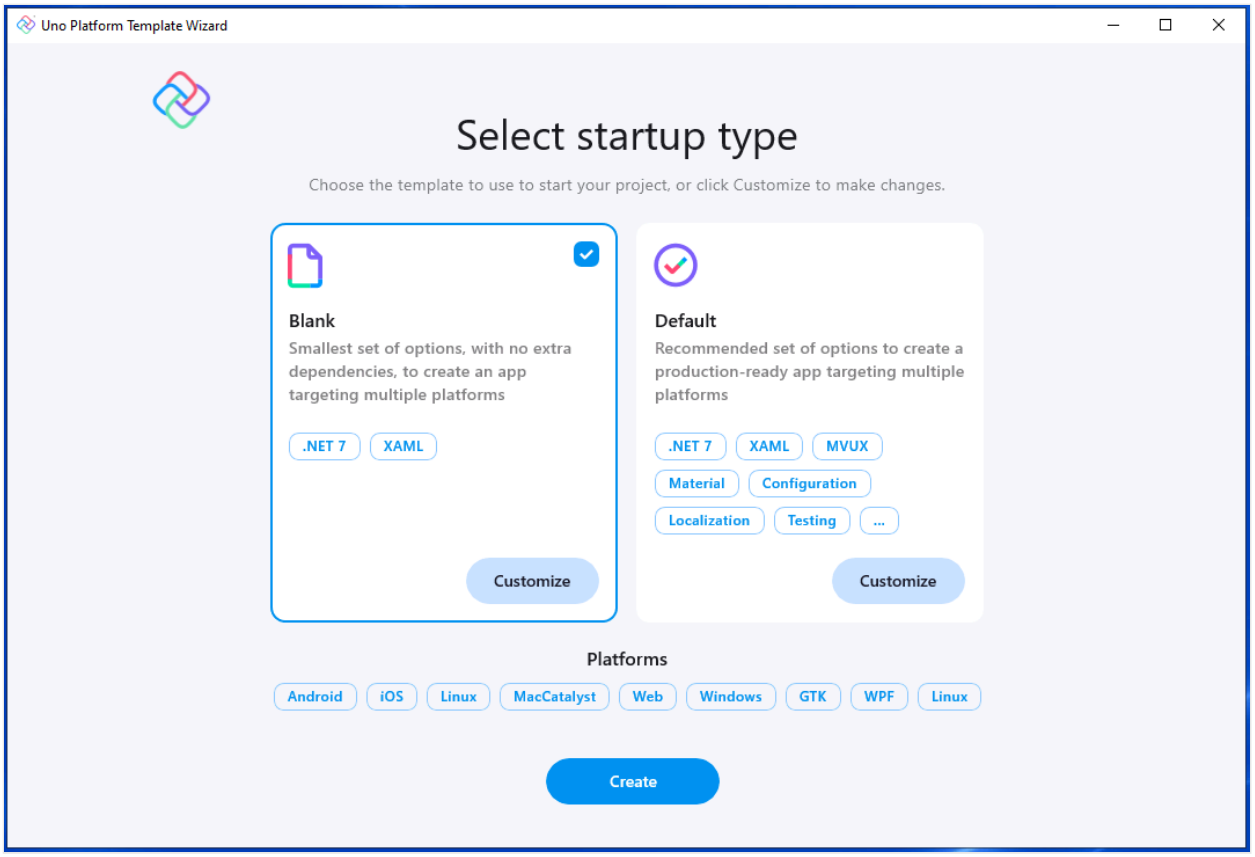
Create a new C# solution using the **Uno Platform App** type from Visual Studio's **Start Page**. To avoid conflicting with the code from the previous tutorial, we'll give this solution a different name, "UnoSimplePhotos". Specify the project name, solution name,

and directory. In this example, our `UnoSimplePhotos` multi-platform project belongs to a `UnoSimplePhotos` solution, which will live in C:\Projects:



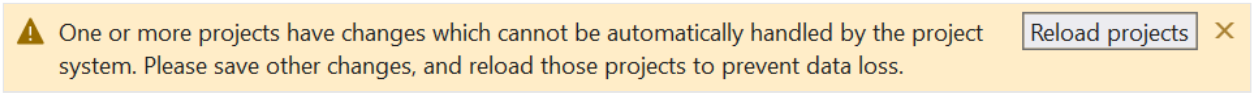
Now you'll choose a base template to take your Simple Photo gallery application multi-platform.

The Uno Platform App template comes with two preset options that allow you to quickly get started with either a **Blank** solution or the **Default** configuration which includes references to the Uno.Material and Uno.Toolkit libraries. The Default configuration also includes Uno.Extensions which is used for dependency injection, configuration, navigation, and logging. In addition, it uses MVUX in place of MVVM, making it a great starting point for rapidly building real-world applications.

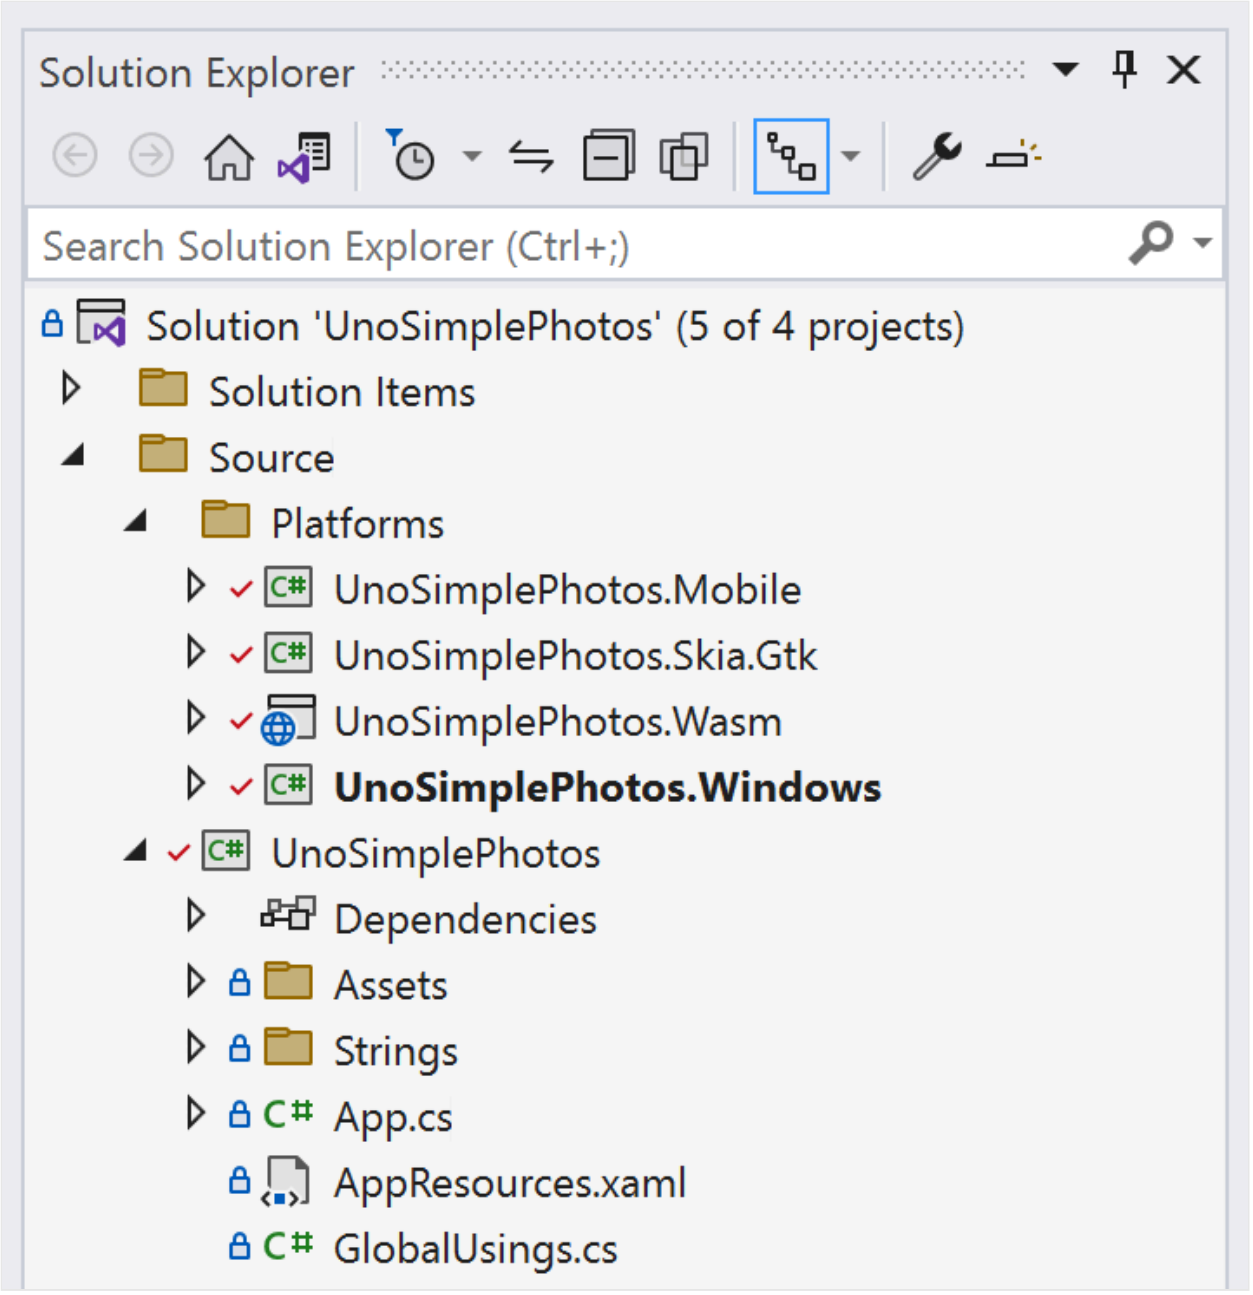


To keep things simple, select the **Blank** preset. Then, click the **Create** button. Wait for the projects to be created and their dependencies to be restored.

A banner at the top of the editor may ask to reload projects, click **Reload projects**:



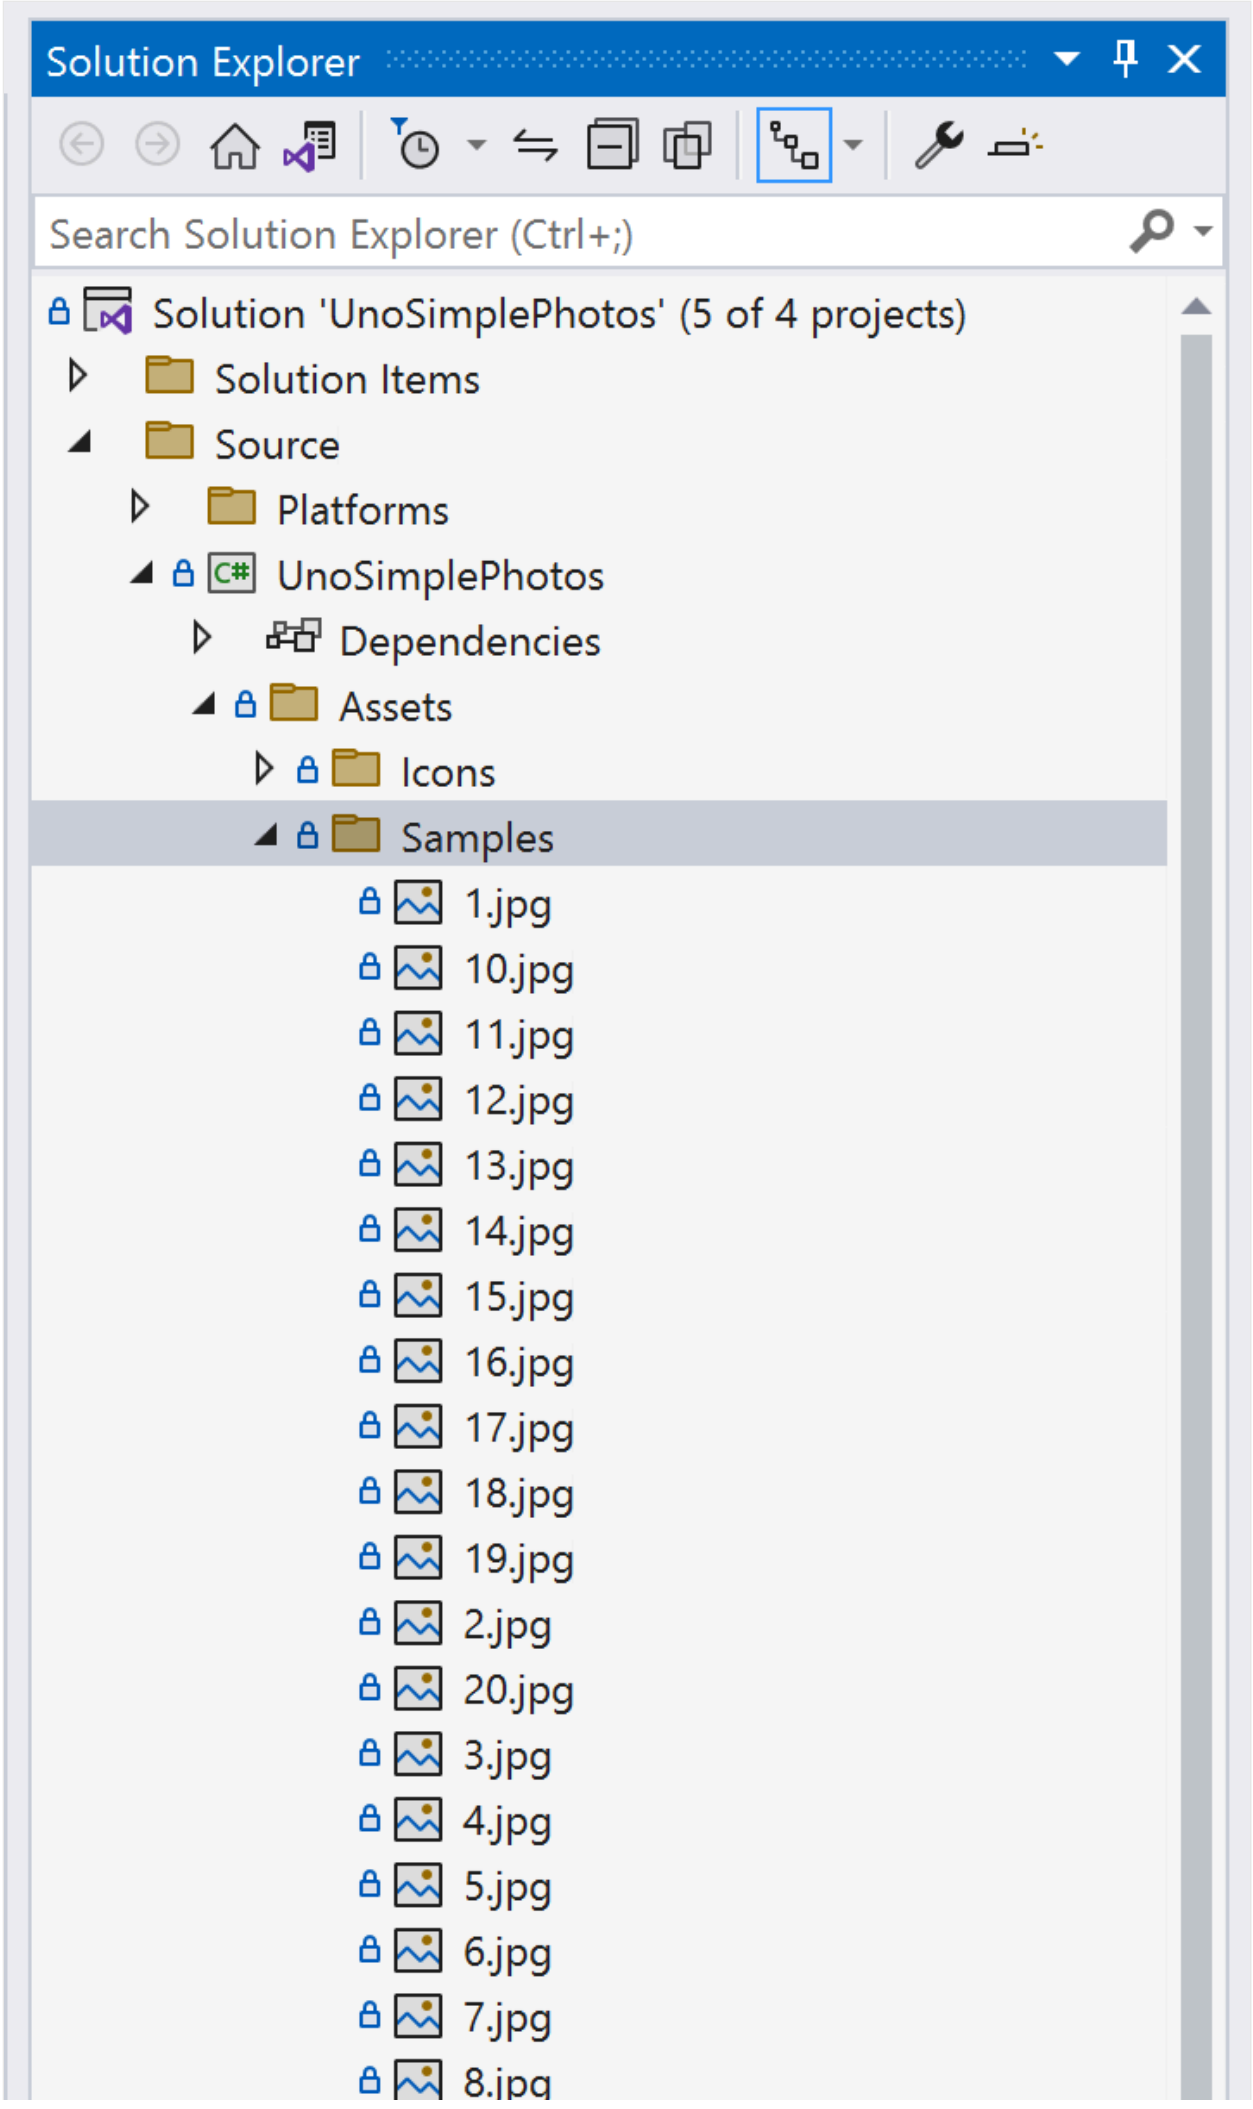
You should see the following default file structure in your **Solution Explorer**:



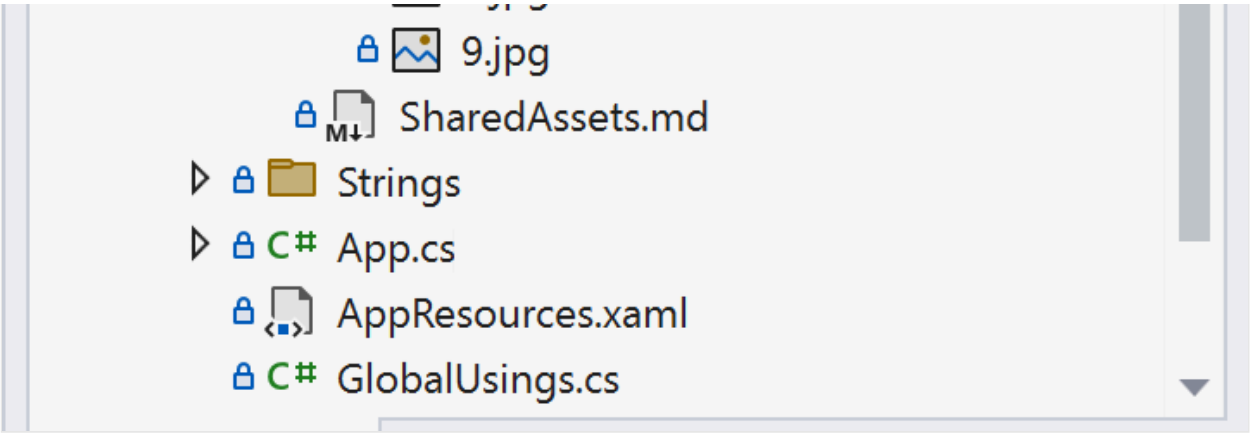
Add image assets to the project

Your app will need some images to display. You can use the same images from the previous tutorial.

In the `UnoSimplePhotos` project, create a new folder named `Assets` and copy the JPG image files to a `Samples` subfolder. The `Assets` folder structure should now look like this:



Solution Explorer
Search Solution Explorer (Ctrl+;)
Solution 'UnoSimplePhotos' (5 of 4 projects)
Solution Items
Source
Platforms
UnoSimplePhotos
Dependencies
Assets
Icons
Samples
1.jpg
10.jpg
11.jpg
12.jpg
13.jpg
14.jpg
15.jpg
16.jpg
17.jpg
18.jpg
19.jpg
2.jpg
20.jpg
3.jpg
4.jpg
5.jpg
6.jpg
7.jpg
8.jpg



For more information on creating the `Assets` folder and adding images to it, see the Uno Platform documentation about Assets and image display.

Preparing your app

Now that you've generated the functional starting point of your multi-platform WinUI application, you can copy code into it from the desktop project.

Copy the view

Because Uno Platform allows you to use the XAML flavor you're already familiar with, you can copy the same code over that you created in the previous tutorial.

Return to the **SimplePhotos** project from the previous tutorial. In the **Solution Explorer**, find the file named `MainWindow.xaml` and open it. Observe that the contents of the view are defined within a `Window` element rather than a `Page`. This is because the desktop project is a WinUI 3 application, which can use `Window` elements to define the contents of the view:

XML

```
<Window x:Class="SimplePhotos.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:local="using:SimplePhotos"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-
compatibility/2006"
        mc:Ignorable="d">

    <Grid>
        <Grid.Resources>
            <DataTemplate x:Key="ImageGridView_ItemTemplate"
                          x:DataType="local:ImageFileInfo">
                <Grid Height="300"
```

```
                      Width="300"
                      Margin="8">
                    <Grid.RowDefinitions>
                        <RowDefinition />
                        <RowDefinition Height="Auto" />
                    </Grid.RowDefinitions>

                    <Image x:Name="ItemImage"
                           Source="Assets/StoreLogo.png"
                           Stretch="Uniform" />

                    <StackPanel Orientation="Vertical"
                                Grid.Row="1">
                        <TextBlock Text="{x:Bind ImageTitle}"
                                   HorizontalAlignment="Center"
                                   Style="{StaticResource
SubtitleTextBlockStyle}" />
                        <StackPanel Orientation="Horizontal"
                                    HorizontalAlignment="Center">
                            <TextBlock Text="{x:Bind ImageFileType}"
                                       HorizontalAlignment="Center"
                                       Style="{StaticResource
CaptionTextBlockStyle}" />
                            <TextBlock Text="{x:Bind ImageDimensions}"
                                       HorizontalAlignment="Center"
                                       Style="{StaticResource
CaptionTextBlockStyle}"
                                       Margin="8,0,0,0" />
                        </StackPanel>

                        <RatingControl Value="{x:Bind ImageRating}"
                                       IsReadOnly="True"/>
                    </StackPanel>
                </Grid>
            </DataTemplate>

            <Style x:Key="ImageGridView_ItemContainerStyle"
                   TargetType="GridViewItem">
                <Setter Property="Background"
                        Value="Gray"/>
                <Setter Property="Margin"
                        Value="8"/>
            </Style>

            <ItemsPanelTemplate x:Key="ImageGridView_ItemsPanelTemplate">
                    <ItemsWrapGrid Orientation="Horizontal"
                                   HorizontalAlignment="Center"/>
                </ItemsPanelTemplate>
        </Grid.Resources>

        <GridView x:Name="ImageGridView"
                  ItemsSource="{x:Bind Images}"
                  ItemTemplate="{StaticResource ImageGridView_ItemTemplate}"
                  ItemContainerStyle="{StaticResource
ImageGridView_ItemContainerStyle}"
```

```
                  ItemsPanel="{StaticResource
ImageGridView_ItemsPanelTemplate}"

ContainerContentChanging="ImageGridView_ContainerContentChanging" />
    </Grid>
</Window>
```

Uno Platform's multi-platform implementation of the controls found in the `Window` element, such as `GridView`, `Image`, and `RatingControl`, ensure that the view itself will work on all supported platforms with only a trivial amount of effort. Copy the contents of this `Window` and paste them into the `Page` element of the `MainPage.xaml` file in the **UnoSimplePhotos** Uno Platform project. The `MainPage` view XAML should look like this:

XML

```
<Page x:Class="UnoSimplePhotos.MainPage"
      xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
      xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
      xmlns:local="using:UnoSimplePhotos"
      xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
      xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
      mc:Ignorable="d">

    <Grid>
        <Grid.Resources>
            <DataTemplate x:Key="ImageGridView_ItemTemplate"
                          x:DataType="local:ImageFileInfo">
                <Grid Height="300"
                      Width="300"
                      Margin="8">
                    <Grid.RowDefinitions>
                        <RowDefinition />
                        <RowDefinition Height="Auto" />
                    </Grid.RowDefinitions>

                    <Image x:Name="ItemImage"
                           Source="Assets/StoreLogo.png"
                           Stretch="Uniform" />

                    <StackPanel Orientation="Vertical"
                                Grid.Row="1">
                        <TextBlock Text="{x:Bind ImageTitle}"
                                   HorizontalAlignment="Center"
                                   Style="{StaticResource
SubtitleTextBlockStyle}" />
                        <StackPanel Orientation="Horizontal"
                                    HorizontalAlignment="Center">
                            <TextBlock Text="{x:Bind ImageFileType}"
                                       HorizontalAlignment="Center"
                                       Style="{StaticResource
CaptionTextBlockStyle}" />
```

```
                            <TextBlock Text="{x:Bind ImageDimensions}"
                                       HorizontalAlignment="Center"
                                       Style="{StaticResource
CaptionTextBlockStyle}"
                                       Margin="8,0,0,0" />
                        </StackPanel>

                        <RatingControl Value="{x:Bind ImageRating}"
                                       IsReadOnly="True"/>
                    </StackPanel>
                </Grid>
            </DataTemplate>

            <Style x:Key="ImageGridView_ItemContainerStyle"
                   TargetType="GridViewItem">
                <Setter Property="Background"
                        Value="Gray"/>
                <Setter Property="Margin"
                        Value="8"/>
            </Style>

            <ItemsPanelTemplate x:Key="ImageGridView_ItemsPanelTemplate">
                <ItemsWrapGrid Orientation="Horizontal"
                               HorizontalAlignment="Center"/>
            </ItemsPanelTemplate>
        </Grid.Resources>

        <GridView x:Name="ImageGridView"
                  ItemsSource="{x:Bind Images}"
                  ItemTemplate="{StaticResource ImageGridView_ItemTemplate}"
                  ItemContainerStyle="{StaticResource
ImageGridView_ItemContainerStyle}"
                  ItemsPanel="{StaticResource
ImageGridView_ItemsPanelTemplate}"

ContainerContentChanging="ImageGridView_ContainerContentChanging">
        </GridView>
    </Grid>
</Page>
```

You may recall that the desktop solution also had a `MainWindow.xaml.cs` file that contained code-behind which corresponds to the view. In the Uno Platform project, the code-behind for the `MainPage` view we've copied into is contained in the `MainPage.xaml.cs` file.

To bring this code-behind multi-platform, we should first move the following into the `MainPage.xaml.cs` file:

- `Images` property: Provides the `GridView` with an observable collection of image files

- Contents of the constructor: Calls `GetItemsAsync()` to populate the `Images` collection with items representing image files
- Remove the manual modification of the `ImageGridView` control's `ItemsSource` property
- `ImageGridView_ContainerContentChanging` method: Used as part of a strategy to progressively load `GridView` items as they are scrolled into view
- `ShowImage` method: Loads the image files into the `GridView`
- `GetItemsAsync` method: Gets the image asset files from the `Samples` folder
- `LoadImageInfoAsync` method: Constructs an `ImageFileInfo` object from a created `StorageFile`

After moving everything over, `MainPage.xaml.cs` should now look like this:

C#

```
using Microsoft.UI.Xaml.Controls;
using System.Collections.ObjectModel;
using Windows.Storage;
using Windows.Storage.Search;

namespace UnoSimplePhotos;

public sealed partial class MainPage : Page
{
    public ObservableCollection<ImageFileInfo> Images { get; }
    = new ObservableCollection<ImageFileInfo>();

    public MainPage()
    {
        this.InitializeComponent();
        GetItemsAsync();
    }

    private void ImageGridView_ContainerContentChanging(ListViewBase sender,
        ContainerContentChangingEventArgs args)
    {
        if (args.InRecycleQueue)
        {
            var templateRoot = args.ItemContainer.ContentTemplateRoot as
Grid;
            var image = templateRoot.FindName("ItemImage") as Image;
            image.Source = null;
        }

        if (args.Phase == 0)
        {
```

```
            args.RegisterUpdateCallback(ShowImage);
            args.Handled = true;
        }
    }

    private async void ShowImage(ListViewBase sender,
ContainerContentChangingEventArgs args)
    {
        if (args.Phase == 1)
        {
            // It's phase 1, so show this item's image.
            var templateRoot = args.ItemContainer.ContentTemplateRoot as
Grid;
            var image = templateRoot.FindName("ItemImage") as Image;
            var item = args.Item as ImageFileInfo;
            image.Source = await item.GetImageThumbnailAsync();
        }
    }

    private async Task GetItemsAsync()
    {
        StorageFolder appInstalledFolder =
Package.Current.InstalledLocation;
        StorageFolder picturesFolder = await
appInstalledFolder.GetFolderAsync("Assets\\Samples");

        var result = picturesFolder.CreateFileQueryWithOptions(new
QueryOptions());

        IReadOnlyList<StorageFile> imageFiles = await
result.GetFilesAsync();
        foreach (StorageFile file in imageFiles)
        {
            Images.Add(await LoadImageInfoAsync(file));
        }
    }

    public async static Task<ImageFileInfo> LoadImageInfoAsync(StorageFile
file)
    {
        var properties = await file.Properties.GetImagePropertiesAsync();
        ImageFileInfo info = new(properties,
                                 file, file.DisplayName,
file.DisplayType);

        return info;
    }
}
```

> **Note**
>
> The files in your Uno app project should use `UnoSimplePhotos` as the namespace.

So far, the files for the main view we're working with contain all the capabilities of the desktop solution. After we copy over the `ImageFileInfo.cs` model file, we will learn how to modify the desktop-oriented blocks of code for multi-platform compatibility.

Copy `ImageFileInfo` from the desktop project and paste it into the `ImageFileInfo.cs` file. Make the following changes:

- Rename the namespace to be `UnoSimplePhotos` instead of `SimplePhotos`:

  C#

  ```
  // Found towards the top of the file
  namespace UnoSimplePhotos;
  ```

- Change the parameter type of the `OnPropertyChanged` method to be nullable:

  C#

  ```
  // string -> string?
  protected void OnPropertyChanged([CallerMemberName] string?
  propertyName = null)
  ...
  ```

- Make the `PropertyChangedEventHandler` nullable:

  C#

  ```
  // PropertyChangedEventHandler -> PropertyChangedEventHandler?
  public event PropertyChangedEventHandler? PropertyChanged;
  ```

Put together, the file should look like this:

C#

```
using Microsoft.UI.Xaml.Media.Imaging;
using System.ComponentModel;
using System.Runtime.CompilerServices;
using Windows.Storage;
using Windows.Storage.FileProperties;
using Windows.Storage.Streams;
using ThumbnailMode = Windows.Storage.FileProperties.ThumbnailMode;

namespace UnoSimplePhotos;

public class ImageFileInfo : INotifyPropertyChanged
{
    public ImageFileInfo(ImageProperties properties,
```

```
        StorageFile imageFile,
        string name,
        string type)
    {
        ImageProperties = properties;
        ImageName = name;
        ImageFileType = type;
        ImageFile = imageFile;
        var rating = (int)properties.Rating;
        var random = new Random();
        ImageRating = rating == 0 ? random.Next(1, 5) : rating;
    }

    public StorageFile ImageFile { get; }

    public ImageProperties ImageProperties { get; }

    public async Task<BitmapImage> GetImageSourceAsync()
    {
        using IRandomAccessStream fileStream = await
ImageFile.OpenReadAsync();

        // Create a bitmap to be the image source.
        BitmapImage bitmapImage = new();
        bitmapImage.SetSource(fileStream);

        return bitmapImage;
    }

    public async Task<BitmapImage> GetImageThumbnailAsync()
    {
        StorageItemThumbnail thumbnail =
            await ImageFile.GetThumbnailAsync(ThumbnailMode.PicturesView);
        // Create a bitmap to be the image source.
        var bitmapImage = new BitmapImage();
        bitmapImage.SetSource(thumbnail);
        thumbnail.Dispose();

        return bitmapImage;
    }

    public string ImageName { get; }

    public string ImageFileType { get; }

    public string ImageDimensions => $"{ImageProperties.Width} x
{ImageProperties.Height}";

    public string ImageTitle
    {
        get => string.IsNullOrEmpty(ImageProperties.Title) ? ImageName :
ImageProperties.Title;
        set
        {
            if (ImageProperties.Title != value)
```

```
            {
                ImageProperties.Title = value;
                _ = ImageProperties.SavePropertiesAsync();
                OnPropertyChanged();
            }
        }
    }

    public int ImageRating
    {
        get => (int)ImageProperties.Rating;
        set
        {
            if (ImageProperties.Rating != value)
            {
                ImageProperties.Rating = (uint)value;
                _ = ImageProperties.SavePropertiesAsync();
                OnPropertyChanged();
            }
        }
    }

    public event PropertyChangedEventHandler? PropertyChanged;

    protected void OnPropertyChanged([CallerMemberName] string? propertyName
= null) =>
        PropertyChanged?.Invoke(this, new
PropertyChangedEventArgs(propertyName));
}
```

This class will serve as a model to represent the image files in the `GridView`. Although it should technically possible to run the app at this point, it may not render the images correctly or display their properties. In the next sections, we'll make a set of changes to these copied files to make them compatible in a multi-platform context.

Using preprocessor directives

In the desktop project from the previous tutorial, the `MainPage.xaml.cs` file contains a `GetItemsAsync` method that enumerates items from a `StorageFolder` representing the installed package location. Because that location is not available on certain platforms such as WebAssembly, we'll need to make changes to this method to make it compatible with all platforms. We'll accordingly make some changes to the `ImageFileInfo` class to ensure compatibility.

First, make the required changes to the `GetItemsAsync` method. Replace the `GetItemsAsync` method in the `MainPage.xaml.cs` file with the following code:

C#

```
private async Task GetItemsAsync()
{
#if WINDOWS
    StorageFolder appInstalledFolder = Package.Current.InstalledLocation;
    StorageFolder picturesFolder = await
appInstalledFolder.GetFolderAsync("UnoSimplePhotos\\Assets\\Samples");

    var result = picturesFolder.CreateFileQueryWithOptions(new
QueryOptions());

    IReadOnlyList<StorageFile> imageFiles = await result.GetFilesAsync();
#else
    var imageFileNames = Enumerable.Range(1, 20).Select(i => new Uri($"ms-
appx:///UnoSimplePhotos/Assets/Samples/{i}.jpg"));
    var imageFiles = new List<StorageFile>();

    foreach (var file in imageFileNames)
    {
        imageFiles.Add(await
StorageFile.GetFileFromApplicationUriAsync(file));
    }
#endif
    foreach (StorageFile file in imageFiles)
    {
        Images.Add(await LoadImageInfoAsync(file));
    }
}
```

This method now uses a **preprocessor directive** to determine which code to execute based on the platform. On Windows, the method gets the `StorageFolder` representing the installed package location and returns the `Samples` folder from it. On other platforms, the method counts up to 20, getting the image files from the `Samples` folder using a `Uri` to represent the image file.

Next, adjust the `LoadImageInfoAsync` method to accommodate the changes we made to the `GetItemsAsync` method. Replace the `LoadImageInfoAsync` method in the `MainPage.xaml.cs` file with the following code:

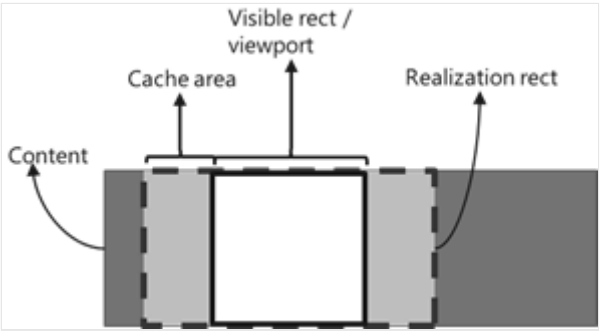
C#

```
public async static Task<ImageFileInfo> LoadImageInfoAsync(StorageFile file)
{
#if WINDOWS
    var properties = await file.Properties.GetImagePropertiesAsync();
    ImageFileInfo info = new(properties,
                                file, file.DisplayName, $"{file.FileType}
file");
#else
    ImageFileInfo info = new(file, file.DisplayName, $"{file.FileType}
```

```
file");
#endif
    return info;
}
```

Similar to the `GetItemsAsync` method, this method now uses a preprocessor directive to determine which code to execute based on the platform. On Windows, the method gets the `ImageProperties` from the `StorageFile` and uses it to create an `ImageFileInfo` object. On other platforms, the method constructs an `ImageFileInfo` object without the `ImageProperties` parameter. Later, modifications will be made to the `ImageFileInfo` class to accommodate this change.

Controls like `GridView` allow for **progressive loading** of updated item container content as they are scrolled into the viewport. This is done by using the `ContainerContentChanging` event. In the desktop project from the previous tutorial, the `ImageGridView_ContainerContentChanging` method uses this event to load the image files into the `GridView`. Because certain aspects of this event are not supported on all platforms, we'll need to make changes to this method to make it compatible with them.



For instance, the `ContainerContentChangingEventArgs.Phase` property is currently unsupported on platforms other than Windows. We'll need to make changes to the `ImageGridView_ContainerContentChanging` method to accommodate this change. Replace the `ImageGridView_ContainerContentChanging` method in the `MainPage.xaml.cs` file with the following code:

C#

```
private void ImageGridView_ContainerContentChanging(
ListViewBase sender,
ContainerContentChangingEventArgs args)
{

    if (args.InRecycleQueue)
    {
        var templateRoot = args.ItemContainer.ContentTemplateRoot as Grid;
        var image = templateRoot?.FindName("ItemImage") as Image;
        if (image is not null)
```

```
        {
            image.Source = null;
        }
    }

#if WINDOWS
        if (args.Phase == 0)
        {
            args.RegisterUpdateCallback(ShowImage);
            args.Handled = true;
        }
#else
    ShowImage(sender, args);
#endif
}
```

The specialized callback is now only registered using `ContainerContentChangingEventArgs.RegisterUpdateCallback()` if the platform is Windows. Otherwise, the `ShowImage` method is called directly. We'll also need to make changes to the `ShowImage` method to work alongside the changes made to the `ImageGridView_ContainerContentChanging` method. Replace the `ShowImage` method in the `MainPage.xaml.cs` file with the following code:

C#

```
private async void ShowImage(ListViewBase sender,
ContainerContentChangingEventArgs args)
{
    if (
#if WINDOWS
            args.Phase == 1
#else
        true
#endif
        )
    {

        // It's phase 1, so show this item's image.
        var templateRoot = args.ItemContainer.ContentTemplateRoot as Grid;
        var image = templateRoot?.FindName("ItemImage") as Image;
        var item = args.Item as ImageFileInfo;
#if WINDOWS
        if (image is not null && item is not null)
        {
            image.Source = await item.GetImageThumbnailAsync();
        }
#else
        if (item is not null)
        {
            await item.GetImageSourceAsync();
        }
```

```
#endif
    }
}
```

Again, preprocessor directives ensure that the `ContainerContentChangingEventArgs.Phase` property is only used on platforms where it is supported. We make use of the previously unused `GetImageSourceAsync()` method to load the image files into the `GridView` on platforms other than Windows. At this point, we'll accommodate the changes made above by editing the `ImageFileInfo` class.

Creating a separate code path for other platforms

Update `ImageFileInfo.cs` to include a new property called `ImageSource` that will be used to load the image file.

C#

```
public BitmapImage? ImageSource { get; private set; }
```

Because platforms like the web do not support advanced image file properties that are readily available on Windows, we'll add a constructor overload that does not require an `ImageProperties` typed parameter. Add the new overload after the existing one using the following code:

C#

```
public ImageFileInfo(StorageFile imageFile,
    string name,
    string type)
{
    ImageName = name;
    ImageFileType = type;
    ImageFile = imageFile;
}
```

This constructor overload is used to construct an `ImageFileInfo` object on platforms other than Windows. Since we did this, it makes sense to make the `ImageProperties` property nullable. Update the `ImageProperties` property to be nullable using the following code:

C#

```
public ImageProperties? ImageProperties { get; }
```

Update the `GetImageSourceAsync` method to use the `ImageSource` property instead of only returning a `BitmapImage` object. Replace the `GetImageSourceAsync` method in the `ImageFileInfo.cs` file with the following code:

C#

```
public async Task<BitmapImage> GetImageSourceAsync()
{
    using IRandomAccessStream fileStream = await ImageFile.OpenReadAsync();

    // Create a bitmap to be the image source.
    BitmapImage bitmapImage = new();
    bitmapImage.SetSource(fileStream);

    ImageSource = bitmapImage;
    PropertyChanged?.Invoke(this, new
PropertyChangedEventArgs(nameof(ImageSource)));

    return bitmapImage;
}
```

To prevent getting the value of `ImageProperties` when it's null, make the following changes:

- Modify the `ImageDimensions` property to use the null conditional operator:

  C#

  ```
  public string ImageDimensions => $"{ImageProperties?.Width} x
  {ImageProperties?.Height}";
  ```

- Change the `ImageTitle` property to use the null conditional operator:

  C#

  ```
  public string ImageTitle
  {
      get => string.IsNullOrEmpty(ImageProperties?.Title) ? ImageName :
  ImageProperties?.Title;
      set
      {
          if (ImageProperties is not null)
          {
              if (ImageProperties.Title != value)
              {
                  ImageProperties.Title = value;
                  _ = ImageProperties.SavePropertiesAsync();
                  OnPropertyChanged();
              }
  ```

```
        }
    }
}
```

- Change `ImageRating` to not rely on `ImageProperties` by generating a random star rating for demonstration purposes:

```
C#

public int ImageRating
{
    get => (int)((ImageProperties?.Rating == null ||
ImageProperties.Rating == 0) ? (uint)Random.Shared.Next(1, 5) :
ImageProperties.Rating);
    set
    {
        if (ImageProperties is not null)
        {
            if (ImageProperties.Rating != value)
            {
                ImageProperties.Rating = (uint)value;
                _ = ImageProperties.SavePropertiesAsync();
                OnPropertyChanged();
            }
        }
    }
}
```

- Update the constructor that generates a random integer to no longer do this:

```
C#

public ImageFileInfo(ImageProperties properties,
    StorageFile imageFile,
    string name,
    string type)
{
    ImageProperties = properties;
    ImageName = name;
    ImageFileType = type;
    ImageFile = imageFile;
}
```

With these edits, the `ImageFileInfo` class should contain the following code. It now has a newly-separated code path for platforms other than Windows:

```
C#
```

```
using Microsoft.UI.Xaml.Media.Imaging;
using System.ComponentModel;
using System.Runtime.CompilerServices;
using Windows.Storage;
using Windows.Storage.FileProperties;
using Windows.Storage.Streams;
using ThumbnailMode = Windows.Storage.FileProperties.ThumbnailMode;

namespace UnoSimplePhotos;

public class ImageFileInfo : INotifyPropertyChanged
{
    public BitmapImage? ImageSource { get; private set; }

    public ImageFileInfo(ImageProperties properties,
        StorageFile imageFile,
        string name,
        string type)
    {
        ImageProperties = properties;
        ImageName = name;
        ImageFileType = type;
        ImageFile = imageFile;
    }

    public ImageFileInfo(StorageFile imageFile,
        string name,
        string type)
    {
        ImageName = name;
        ImageFileType = type;
        ImageFile = imageFile;
    }

    public StorageFile ImageFile { get; }

    public ImageProperties? ImageProperties { get; }

    public async Task<BitmapImage> GetImageSourceAsync()
    {
        using IRandomAccessStream fileStream = await
ImageFile.OpenReadAsync();

        // Create a bitmap to be the image source.
        BitmapImage bitmapImage = new();
        bitmapImage.SetSource(fileStream);

        ImageSource = bitmapImage;
        PropertyChanged?.Invoke(this, new
PropertyChangedEventArgs(nameof(ImageSource)));

        return bitmapImage;
    }
```

```
    public async Task<BitmapImage> GetImageThumbnailAsync()
    {
        StorageItemThumbnail thumbnail =
            await ImageFile.GetThumbnailAsync(ThumbnailMode.PicturesView);
        // Create a bitmap to be the image source.
        var bitmapImage = new BitmapImage();
        bitmapImage.SetSource(thumbnail);
        thumbnail.Dispose();

        return bitmapImage;
    }

    public string ImageName { get; }

    public string ImageFileType { get; }

    public string ImageDimensions => $"{ImageProperties?.Width} x
{ImageProperties?.Height}";

    public string ImageTitle
    {
        get => string.IsNullOrEmpty(ImageProperties?.Title) ? ImageName :
ImageProperties.Title;
        set
        {
            if (ImageProperties is not null)
            {
                if (ImageProperties.Title != value)
                {
                    ImageProperties.Title = value;
                    _ = ImageProperties.SavePropertiesAsync();
                    OnPropertyChanged();
                }
            }
        }
    }

    public int ImageRating
    {
        get => (int)((ImageProperties?.Rating == null ||
ImageProperties.Rating == 0) ? (uint)Random.Shared.Next(1, 5) :
ImageProperties.Rating);
        set
        {
            if (ImageProperties is not null)
            {
                if (ImageProperties.Rating != value)
                {
                    ImageProperties.Rating = (uint)value;
                    _ = ImageProperties.SavePropertiesAsync();
                    OnPropertyChanged();
                }
            }
        }
    }
```

```
    public event PropertyChangedEventHandler? PropertyChanged;

    protected void OnPropertyChanged([CallerMemberName] string? propertyName
= null) =>
        PropertyChanged?.Invoke(this, new
PropertyChangedEventArgs(propertyName));
}
```

This `ImageFileInfo` class is used to represent the image files in the `GridView`. Finally, we'll make changes to the `MainPage.xaml` file to accommodate the changes to the model.

Using platform-specific XAML markup

There are a couple of items in our view markup which should only be evaluated on Windows. Add a new namespace on the `Page` element of the `MainPage.xaml` file like this:

XML

```
...
xmlns:win="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
```

Now, in `MainPage.xaml`, replace the `ItemsPanel` property setter on the `GridView` element with the following code:

XML

```
win:ItemsPanel="{StaticResource ImageGridView_ItemsPanelTemplate}"
```

Prepending the property name with `win:` ensures that the property is only set on Windows. Do this again within the `ImageGridView_ItemTemplate` resource. We want to only load elements that use the `ImageDimensions` property on Windows. Replace the `TextBlock` element that uses the `ImageDimensions` property with the following code:

XML

```
<win:TextBlock Text="{x:Bind ImageDimensions}"
               HorizontalAlignment="Center"
               Style="{StaticResource CaptionTextBlockStyle}"
               Margin="8,0,0,0" />
```

The `MainPage.xaml` file should now look like this:

XML

```
<Page x:Class="UnoSimplePhotos.MainPage"
      xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
      xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
      xmlns:local="using:UnoSimplePhotos"
      xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
      xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
      xmlns:win="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
      mc:Ignorable="d"
      Background="{ThemeResource ApplicationPageBackgroundThemeBrush}">

    <Grid>
        <Grid.Resources>
            <DataTemplate x:Key="ImageGridView_ItemTemplate"
                          x:DataType="local:ImageFileInfo">
                <Grid Height="300"
                      Width="300"
                      Margin="8">
                    <Grid.RowDefinitions>
                        <RowDefinition />
                        <RowDefinition Height="Auto" />
                    </Grid.RowDefinitions>

                    <Image x:Name="ItemImage"
                           Source="{x:Bind ImageSource}"
                           Stretch="Uniform" />

                    <StackPanel Orientation="Vertical"
                                Grid.Row="1">
                        <TextBlock Text="{x:Bind ImageTitle}"
                                   HorizontalAlignment="Center"
                                   Style="{StaticResource
SubtitleTextBlockStyle}" />
                        <StackPanel Orientation="Horizontal"
                                    HorizontalAlignment="Center">
                            <TextBlock Text="{x:Bind ImageFileType}"
                                       HorizontalAlignment="Center"
                                       Style="{StaticResource
CaptionTextBlockStyle}" />
                            <win:TextBlock Text="{x:Bind ImageDimensions}"
                                           HorizontalAlignment="Center"
                                           Style="{StaticResource
CaptionTextBlockStyle}"
                                           Margin="8,0,0,0" />
                        </StackPanel>

                        <RatingControl Value="{x:Bind ImageRating}"
                                       IsReadOnly="True" />
                    </StackPanel>
                </Grid>
            </DataTemplate>

            <Style x:Key="ImageGridView_ItemContainerStyle"
```

```
                    TargetType="GridViewItem">
                <Setter Property="Background"
                        Value="Gray" />
                <Setter Property="Margin"
                        Value="8"/>
            </Style>

            <ItemsPanelTemplate x:Key="ImageGridView_ItemsPanelTemplate">
                <ItemsWrapGrid Orientation="Horizontal"
                               HorizontalAlignment="Center"/>
            </ItemsPanelTemplate>
        </Grid.Resources>

        <GridView x:Name="ImageGridView"
                  ItemsSource="{x:Bind Images, Mode=OneWay}"
                  win:ItemsPanel="{StaticResource
ImageGridView_ItemsPanelTemplate}"

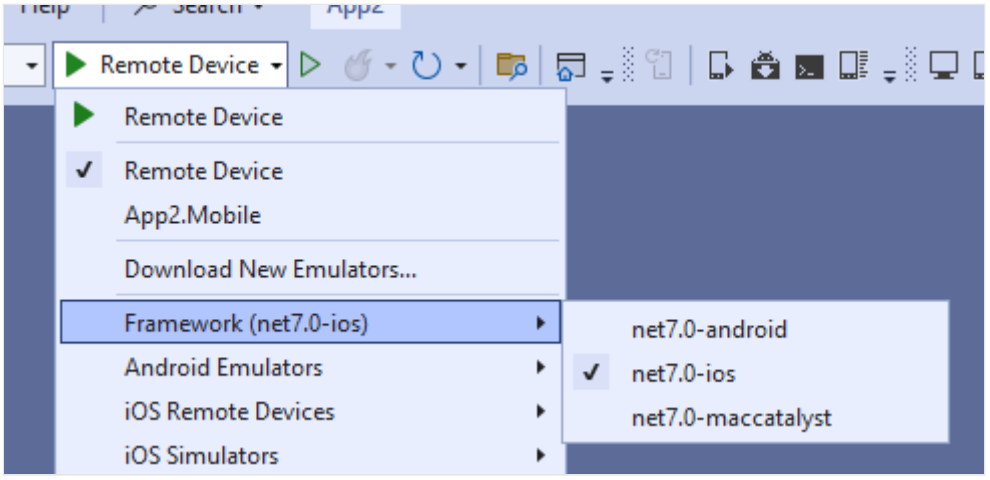
ContainerContentChanging="ImageGridView_ContainerContentChanging"
                  ItemContainerStyle="{StaticResource
ImageGridView_ItemContainerStyle}"
                  ItemTemplate="{StaticResource ImageGridView_ItemTemplate}"
/>
    </Grid>
</Page>
```

Running the app

Launch the `UnoSimplePhotos.Windows` target. Observe that this WinUI app is very similar to the previous tutorial.

You can now build and run your app on any of the supported platforms. To do so, you can use the debug toolbar drop-down to select a target platform to deploy:

- To run the **WebAssembly** (Wasm) head:
  - Right-click on the `UnoSimplePhotos.Wasm` project, select **Set as startup project**
  - Press the `UnoSimplePhotos.Wasm` button to deploy the app
  - If desired, you can add and use the `UnoSimplePhotos.Server` project as an alternative
- To debug for **iOS**:
  - Right-click on the `UnoSimplePhotos.Mobile` project, and select **Set as startup project**
  - In the debug toolbar drop-down, select an active iOS device or the simulator. You'll need to be paired with a Mac for this to work.



- To debug for **Mac Catalyst**:
  - Right-click on the `UnoSimplePhotos.Mobile` project, and select **Set as startup project**
  - In the debug toolbar drop-down, select a remote macOS device. You'll need to be paired with one for this to work.

- To debug the **Android** platform:
  - Right-click on the `UnoSimplePhotos.Mobile` project, and select **Set as startup project**
  - In the debug toolbar drop-down, select either an active Android device or the emulator
    - Select an active device in the "Device" sub-menu

- To debug on **Linux** with **Skia GTK**:
  - Right-click on the `UnoSimplePhotos.Skia.Gtk` project, and select **Set as startup project**
  - Press the `UnoSimplePhotos.Skia.Gtk` button to deploy the app

WinUI

Article • 11/08/2024

Important

At this time, there are two generations of WinUI: **WinUI 2 for UWP** and **WinUI in the Windows App SDK (WinUI 3)**. While both can be used in production-ready apps on Windows 10 and later, each have different development targets.

See **Comparison of WinUI 3 and WinUI 2**.

WinUI is a native user experience (UX) framework for both Windows desktop and UWP applications.

By incorporating the Fluent Design System into all experiences, controls, and styles, WinUI provides consistent, intuitive, and accessible experiences using the latest user interface (UI) patterns.

With support for both desktop and UWP apps, you can build with WinUI from the ground up, or gradually migrate your existing MFC, WinForms, or WPF apps using familiar languages such as C++, C#, Visual Basic, and JavaScript (using React Native for Desktop).

> The WinUI libraries are hosted in the WinUI GitHub repo where you can file feature requests or bugs, and interact with the WinUI team.

Comparison of WinUI 3 and WinUI 2

The following table highlights some of most significant differences between WinUI 3 in the Windows App SDK and WinUI 2 for UWP.

Expand table

WinUI 3 in the Windows App SDK	WinUI 2 for UWP
WinUI 3 ships with the Windows App SDK.	**WinUI 2**, the 2nd generation of WinUI, ships as a standalone NuGet package, and is integrated with Windows SDKs.
UX stack and control library completely decoupled from the OS and Windows SDKs, including the core framework, composition, and input layers of the UX stack.	UX stack and control library tightly coupled to the OS and Windows SDKs.
WinUI 3 can be used to build production-ready **desktop/Win32** Windows apps.	WinUI 2 can be used in UWP applications and incorporated into desktop applications using XAML Islands (for installation instructions, see Getting started with the WinUI 2 Library).
WinUI 3 ships as a component of the Windows App SDK framework package, with Visual Studio project templates in the Windows App SDK Visual Studio Extension (VSIX).	Part of WinUI 2 ships within the operating system itself (the Windows.UI.* family of UWP WinRT APIs) and part of it ships as a library ("WinUI 2") with additional controls, elements and the latest styles on top of what's already included in the operating system itself. With WinUI 2, these features ship in a downloadable NuGet package. However, other significant parts of the UI stack are still built-in to the OS, such as the core XAML framework, input, and composition layers.
WinUI 3 supports C# (.NET 6 and later) and C++ for desktop apps.	WinUI 2 supports C# and Visual Basic (.NET Native), and C++ apps.
WinUI 3 is supported only in desktop-based projects. To use WinUI 3, UWP projects can migrate their project type to desktop (see how to migrate your UWP app to the Windows App SDK).	WinUI 2 can be incorporated into production UWP apps by installing a NuGet package into a new or existing UWP project. WinUI controls and styles can then be referenced directly in new apps, or by updating "Windows.UI." namespace references to "Microsoft.UI." in existing apps.
WinUI 3 supports the Chromium-based WebView2 control	WinUI 2 supports the WebView control on all devices, and starting with WinUI 2.8, the WebView2 control on Desktop.
WinUI 3 works downlevel to Windows 10 October 2018	WinUI 2.0 - 2.7 works downlevel to Windows 10 Creators Update (Version 1703, OS build 15063). WinUI 2.8 and later

WinUI 3 in the Windows App SDK	WinUI 2 for UWP
Update (Version 1809, OS build 17763).	works downlevel to Windows 10 October 2018 Update (Version 1809, OS build 17763).

WinUI in the Windows App SDK (WinUI 3)

Article • 07/15/2024

WinUI 3 is the native UI platform component that ships with the Windows App SDK (completely decoupled from Windows SDKs). The Windows App SDK provides a unified set of APIs and tools that can be used to create production desktop apps that target Windows 10 and later, and can be published to the Microsoft Store.

> **Important**
>
> The **Windows App SDK** was previously known as **Project Reunion**. Some assets, such as the VSIX extension and NuGet packages, still use this code name (these will be renamed in a future release).
>
> **Windows App SDK** is used in all documentation except where a specific release or asset still refers to **Project Reunion**.

Create your first WinUI 3 project

WinUI resources

Release notes: For more details on the Windows App SDK, see Latest stable channel release notes for the Windows App SDK.

Github: WinUI is hosted on Github. Use the WinUI repo, to file feature requests or bugs, and interact with the WinUI team.

Examples

> **Tip**
>
> For more info, design guidance, and code examples, see **Design and code Windows apps**.
>
> The **WinUI 3 Gallery** and **WinUI 2 Gallery** apps include interactive examples of most WinUI 3 and WinUI 2 controls, features, and functionality.

If installed already, open them by clicking the following links: **WinUI 3 Gallery** or **WinUI 2 Gallery**.

If they are not installed, you can download the **WinUI 3 Gallery** and the **WinUI 2 Gallery** from the Microsoft Store.

You can also get the source code for both from **GitHub** (use the *main* branch for WinUI 3 and the *winui2* branch for WinUI 2).

Build a C# .NET app with WinUI 3 and Win32 interop

Article • 03/06/2025

In this topic, we step through how to build a basic **C# .NET** application with WinUI 3 and Win32 interop capabilities using Platform Invocation Services (PInvoke).

Prerequisites

1. Start developing Windows apps

Basic managed C#/.NET app

For this example, we'll specify the location and size of the app window, convert and scale it for the appropriate DPI, disable the window minimize and maximize buttons, and finally query the current process to show a list of the modules that are loaded into the current process.

We're going to build our example app from the initial template application (see Prerequisites). Also see WinUI 3 templates in Visual Studio.

The MainWindow.xaml file

With WinUI 3, you can create instances of the Window class in XAML markup.

The XAML Window class has been extended to support desktop windows, turning it into an abstraction of each of the low-level window implementations used by the UWP and desktop app models. Specifically, CoreWindow for UWP and window handles (or HWNDs) for Win32.

The following code shows the MainWindow.xaml file from the initial template app, which uses the Window class as the root element for the app.

XAML

```
<Window
    x:Class="WinUI_3_basic_win32_interop.MainWindow"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:WinUI_3_basic_win32_interop"
    xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
```

```
    xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
    mc:Ignorable="d">

    <StackPanel Orientation="Horizontal" HorizontalAlignment="Center"
VerticalAlignment="Center">
        <Button x:Name="myButton" Click="myButton_Click">Click Me</Button>
    </StackPanel>
</Window>
```

Configuration

1. To call Win32 APIs exported from `User32.dll`, you can use the **C#/Win32 P/Invoke Source Generator** in your Visual Studio project. Click **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution...**, and (on the **Browse** tab) search for *Microsoft.Windows.CsWin32*. For more details, see Calling Native Functions from Managed Code.

   You can optionally confirm that installation was successful by confirming that *Microsoft.Windows.CsWin32* is listed under the **Dependencies** > **Packages** node in Solution Explorer.

   You can also optionally double-click the application project file (or right click and select **Edit project file**) to open the file in a text editor, and confirm that the project file now includes a NuGet `PackageReference` for "Microsoft.Windows.CsWin32".

   XML

   ```
   <Project Sdk="Microsoft.NET.Sdk">
     <PropertyGroup>
       <OutputType>WinExe</OutputType>
       <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
       <TargetPlatformMinVersion>10.0.17763.0</TargetPlatformMinVersion>
       <RootNamespace>WinUI_3_basic_win32_interop</RootNamespace>
       <ApplicationManifest>app.manifest</ApplicationManifest>
       <Platforms>x86;x64;ARM64</Platforms>
       <RuntimeIdentifiers>win-x86;win-x64;win-arm64</RuntimeIdentifiers>
       <PublishProfile>win-$(Platform).pubxml</PublishProfile>
       <UseWinUI>true</UseWinUI>
       <EnableMsixTooling>true</EnableMsixTooling>
       <Nullable>enable</Nullable>
     </PropertyGroup>

     <ItemGroup>
       <Content Include="Assets\SplashScreen.scale-200.png" />
       <Content Include="Assets\LockScreenLogo.scale-200.png" />
       <Content Include="Assets\Square150x150Logo.scale-200.png" />
       <Content Include="Assets\Square44x44Logo.scale-200.png" />
       <Content Include="Assets\Square44x44Logo.targetsize-24_altform-
   unplated.png" />
   ```

```
    <Content Include="Assets\StoreLogo.png" />
    <Content Include="Assets\Wide310x150Logo.scale-200.png" />
  </ItemGroup>

  <ItemGroup>
    <Manifest Include="$(ApplicationManifest)" />
  </ItemGroup>

  <!--
    Defining the "Msix" ProjectCapability here allows the Single-
project MSIX Packaging
    Tools extension to be activated for this project even if the
Windows App SDK Nuget
    package has not yet been restored.
  -->
  <ItemGroup
Condition="'$(DisableMsixProjectCapabilityAddedByProject)'!='true' and
'$(EnableMsixTooling)'=='true'">
    <ProjectCapability Include="Msix" />
  </ItemGroup>
  <ItemGroup>
    <PackageReference Include="Microsoft.Windows.CsWin32"
Version="0.3.183">
      <PrivateAssets>all</PrivateAssets>
      <IncludeAssets>runtime; build; native; contentfiles; analyzers;
buildtransitive</IncludeAssets>
    </PackageReference>
    <PackageReference Include="Microsoft.Windows.SDK.BuildTools"
Version="10.0.26100.1742" />
    <PackageReference Include="Microsoft.WindowsAppSDK"
Version="1.6.250205002" />
  </ItemGroup>

  <!--
    Defining the "HasPackageAndPublishMenuAddedByProject" property here
allows the Solution
    Explorer "Package and Publish" context menu entry to be enabled for
this project even if
    the Windows App SDK Nuget package has not yet been restored.
  -->
  <PropertyGroup
Condition="'$(DisableHasPackageAndPublishMenuAddedByProject)'!='true'
and '$(EnableMsixTooling)'=='true'">
    <HasPackageAndPublishMenu>true</HasPackageAndPublishMenu>
  </PropertyGroup>

  <!-- Publish Properties -->
  <PropertyGroup>
    <PublishReadyToRun Condition="'$(Configuration)' ==
'Debug'">False</PublishReadyToRun>
    <PublishReadyToRun Condition="'$(Configuration)' !=
'Debug'">True</PublishReadyToRun>
    <PublishTrimmed Condition="'$(Configuration)' ==
'Debug'">False</PublishTrimmed>
    <PublishTrimmed Condition="'$(Configuration)' !=
```

```
'Debug'">True</PublishTrimmed>
  </PropertyGroup>
</Project>
```

2. Add a text file to your project, and name it `NativeMethods.txt`. The contents of this file inform the C#/Win32 P/Invoke Source Generator the functions and types for which you want P/Invoke source code generated. In other words, which functions and types you'll be calling and using in your C# code.

```
C#

GetDpiForWindow
GetWindowLong
SetWindowPos
SetWindowLong
HWND_TOP
WINDOW_STYLE
```

Code

1. In the `App.xaml.cs` code-behind file, we get a handle to the **Window** by using the **WindowNative.GetWindowHandle** WinRT COM interop method (see Retrieve a window handle (HWND)).

   That method is called from the app's **OnLaunched** handler, as shown here:

```
C#

/// <summary>
/// Invoked when the application is launched.
/// </summary>
/// <param name="args">Details about the launch request and process.
</param>
protected override void
OnLaunched(Microsoft.UI.Xaml.LaunchActivatedEventArgs args)
{
    m_window = new MainWindow();

    var hwnd = WinRT.Interop.WindowNative.GetWindowHandle(m_window);

    SetWindowDetails(hwnd, 800, 600);

    m_window.Activate();
}
```

2. We then call a `SetWindowDetails` method, passing the Window handle and preferred dimensions.

In this method:

- We call GetDpiForWindow to get the dots per inch (dpi) value for the window (Win32 uses physical pixels, while WinUI 3 uses effective pixels). This dpi value is used to calculate the scale factor, and apply it to the width and height specified for the window.
- We then call SetWindowPos to specify the desired location of the window.
- Finally, we call SetWindowLong to disable the *Minimize* and *Maximize* buttons.

```
C#

private static void SetWindowDetails(IntPtr hwnd, int width, int
height)
{
    var dpi =
Windows.Win32.PInvoke.GetDpiForWindow((Windows.Win32.Foundation.HWND)hw
nd);
    float scalingFactor = (float)dpi / 96;
    width = (int)(width * scalingFactor);
    height = (int)(height * scalingFactor);

    _ =
Windows.Win32.PInvoke.SetWindowPos((Windows.Win32.Foundation.HWND)hwnd,
                                   Windows.Win32.Foundation.HWND.HWND_TOP,
                                   0, 0, width, height,

Windows.Win32.UI.WindowsAndMessaging.SET_WINDOW_POS_FLAGS.SWP_NOMOVE);

    var nIndex =
Windows.Win32.PInvoke.GetWindowLong((Windows.Win32.Foundation.HWND)hwnd
,

Windows.Win32.UI.WindowsAndMessaging.WINDOW_LONG_PTR_INDEX.GWL_STYLE) &
                ~
(int)Windows.Win32.UI.WindowsAndMessaging.WINDOW_STYLE.WS_MINIMIZEBOX &
                ~
(int)Windows.Win32.UI.WindowsAndMessaging.WINDOW_STYLE.WS_MAXIMIZEBOX;

    _ =
Windows.Win32.PInvoke.SetWindowLong((Windows.Win32.Foundation.HWND)hwnd
,

Windows.Win32.UI.WindowsAndMessaging.WINDOW_LONG_PTR_INDEX.GWL_STYLE,
            nIndex);
}
```

3. In the MainWindow.xaml file, we use a ContentDialog with a ScrollViewer to display a list of all the modules loaded for the current process.

XAML

```
<StackPanel Orientation="Horizontal" HorizontalAlignment="Center"
VerticalAlignment="Center">
    <Button x:Name="myButton" Click="myButton_Click">Display loaded
modules</Button>

    <ContentDialog x:Name="contentDialog" CloseButtonText="Close">
        <ScrollViewer>
            <TextBlock x:Name="cdTextBlock" TextWrapping="Wrap" />
        </ScrollViewer>
    </ContentDialog>

</StackPanel>
```

4. We then replace the `MyButton_Click` event handler with the following code.

   Here, we get a reference to the current process by calling GetCurrentProcess. We then iterate through the collection of Modules and append the filename of each ProcessModule to our display string.

   C#

   ```
   private async void myButton_Click(object sender, RoutedEventArgs e)
   {
       myButton.Content = "Clicked";

       var description = new System.Text.StringBuilder();
       var process = System.Diagnostics.Process.GetCurrentProcess();
       foreach (System.Diagnostics.ProcessModule module in
   process.Modules)
       {
           description.AppendLine(module.FileName);
       }

       cdTextBlock.Text = description.ToString();
       await contentDialog.ShowAsync();
   }
   ```

5. Compile and run the app.

6. After the window appears, select the "Display loaded modules" button.

The basic Win32 interop application described in this topic.

Summary

In this topic we covered accessing the underlying window implementation (in this case Win32 and HWNDs) and using Win32 APIs along with the WinRT APIs. This demonstrates how you can use existing desktop application code when creating new WinUI 3 desktop apps.

For a more extensive sample, see the AppWindow gallery sample in the Windows App SDK Samples GitHub repo.

An example to customize the window title bar

In this second example, we show how to customize the window's title bar and its content. Before following along with it, review these topics:

- Install tools for the Windows App SDK.
- Create your first WinUI 3 project.

Create a new project

1. In Visual Studio, create a new C# or C++/WinRT project from the **Blank App, Packaged (WinUI 3 in Desktop)** project template.

Configuration

1. Again, reference the *Microsoft.Windows.CsWin32* NuGet package just like we did in the first example.

2. Add a `NativeMethods.txt` text file to your project.

```
C#

LoadImage
SendMessage
SetWindowText
WM_SETICON
```

MainWindow.xaml

> **Note**
>
> If you need an icon file to use with this walkthrough, then you can download the computer.ico file from the **WirelessHostednetwork** sample app. Place that file in your `Assets` folder, and add the file to your project as content. You'll then be able to refer to the file using the url `Assets/computer.ico`.
>
> Otherwise, feel free to use an icon file that you already have, and change the two references to it in the code listings below.

1. In the code listing below, you'll see that in `MainWindow.xaml` we've added two buttons, and specified **Click** handlers for each. In the **Click** handler for the first button (**basicButton_Click**), we set the title bar icon and text. In the second (**customButton_Click**), we demonstrate more significant customization by replacing the title bar with the content of the **StackPanel** named *customTitleBarPanel*.

```
XAML

<?xml version="1.0" encoding="utf-8"?>
<Window
    x:Class="window_titlebar.MainWindow"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
```

```
    xmlns:local="using:window_titlebar"
    xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
    xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
    mc:Ignorable="d"
    Title="Basic WinUI 3 Window title bar sample">

    <Grid x:Name="rootElement" RowDefinitions="100, *, 100, *">

        <StackPanel x:Name="customTitleBarPanel" Grid.Row="0"
Orientation="Horizontal" HorizontalAlignment="Stretch"
VerticalAlignment="Top" Visibility="Collapsed">
            <Image Source="Images/windowIcon.gif" />
            <TextBlock VerticalAlignment="Center" Text="Full customization
of title bar"/>
        </StackPanel>

        <StackPanel x:Name="buttonPanel"  Grid.Row="2"
Orientation="Horizontal" HorizontalAlignment="Center">
            <Button x:Name="basicButton" Click="basicButton_Click"
Margin="25">Set the Window title and icon</Button>
            <Button x:Name="customButton" Click="customButton_Click"
Margin="25">Customize the window title bar</Button>
        </StackPanel>

    </Grid>
</Window>
```

MainWindow.xaml.cs/cpp

1. In the code listing below for the **basicButton_Click** handler—in order to keep the custom title bar hidden—we collapse the *customTitleBarPanel* **StackPanel**, and we set the ExtendsContentIntoTitleBar property to `false`.
2. We then call **IWindowNative::get_WindowHandle** (for C#, using the interop helper method **GetWindowHandle**) to retrieve the window handle (**HWND**) of the main window.
3. Next, we set the application icon (for C#, using the PInvoke.User32 NuGet package) by calling the LoadImage and SendMessage functions.
4. Finally, we call SetWindowText to update the title bar string.

C#

```
private void basicButton_Click(object sender, RoutedEventArgs e)
{
    // Ensure the custom title bar content is not displayed.
    customTitleBarPanel.Visibility = Visibility.Collapsed;

    // Disable custom title bar content.
    ExtendsContentIntoTitleBar = false;
```

```
    //Get the Window's HWND
    var hwnd = WinRT.Interop.WindowNative.GetWindowHandle(this);

    var hIcon = Windows.Win32.PInvoke.LoadImage(
        null,
        "Images/windowIcon.ico",
        Windows.Win32.UI.WindowsAndMessaging.GDI_IMAGE_TYPE.IMAGE_ICON,
        20, 20,
        Windows.Win32.UI.WindowsAndMessaging.IMAGE_FLAGS.LR_LOADFROMFILE);

    Windows.Win32.PInvoke.SendMessage(
        (Windows.Win32.Foundation.HWND)hwnd,
        Windows.Win32.PInvoke.WM_SETICON,
        (Windows.Win32.Foundation.WPARAM)0,
        (Windows.Win32.Foundation.LPARAM)hIcon.DangerousGetHandle());

    Windows.Win32.PInvoke.SetWindowText((Windows.Win32.Foundation.HWND)hwnd,
"Basic customization of title bar");
}
```

C++/WinRT

```
// pch.h
...
#include <microsoft.ui.xaml.window.h>
...

// MainWindow.xaml.h
...
void basicButton_Click(Windows::Foundation::IInspectable const& sender,
Microsoft::UI::Xaml::RoutedEventArgs const& args);
...

// MainWindow.xaml.cpp
void MainWindow::basicButton_Click(IInspectable const&, RoutedEventArgs
const&)
{
    // Ensure the that custom title bar content is not displayed.
    customTitleBarPanel().Visibility(Visibility::Collapsed);

    // Disable custom title bar content.
    ExtendsContentIntoTitleBar(false);

    // Get the window's HWND
    auto windowNative{ this->m_inner.as<::IWindowNative>() };
    HWND hWnd{ 0 };
    windowNative->get_WindowHandle(&hWnd);

    HICON icon{ reinterpret_cast<HICON>(::LoadImage(nullptr,
L"Assets/computer.ico", IMAGE_ICON, 0, 0, LR_DEFAULTSIZE | LR_LOADFROMFILE))
};
    ::SendMessage(hWnd, WM_SETICON, 0, (LPARAM)icon);
```

```
    this->Title(L"Basic customization of title bar");
}
```

5. In the **customButton_Click** handler, we set the visibility of the *customTitleBarPanel* **StackPanel** to **Visible**.
6. We then set the ExtendsContentIntoTitleBar property to `true`, and call SetTitleBar to display the *customTitleBarPanel* **StackPanel** as our custom title bar.

C#

```
private void customButton_Click(object sender, RoutedEventArgs e)
{
    customTitleBarPanel.Visibility = Visibility.Visible;

    // Enable custom title bar content.
    ExtendsContentIntoTitleBar = true;
    // Set the content of the custom title bar.
    SetTitleBar(customTitleBarPanel);
}
```

C++/WinRT

```
// MainWindow.xaml.h
...
void customButton_Click(Windows::Foundation::IInspectable const& sender,
Microsoft::UI::Xaml::RoutedEventArgs const& args);
...

// MainWindow.xaml.cpp
void MainWindow::customButton_Click(IInspectable const&, RoutedEventArgs
const&)
{
    customTitleBarPanel().Visibility(Visibility::Visible);

    // Enable custom title bar content.
    ExtendsContentIntoTitleBar(true);

    // Set the content of the custom title bar.
    SetTitleBar(customTitleBarPanel());
}
```

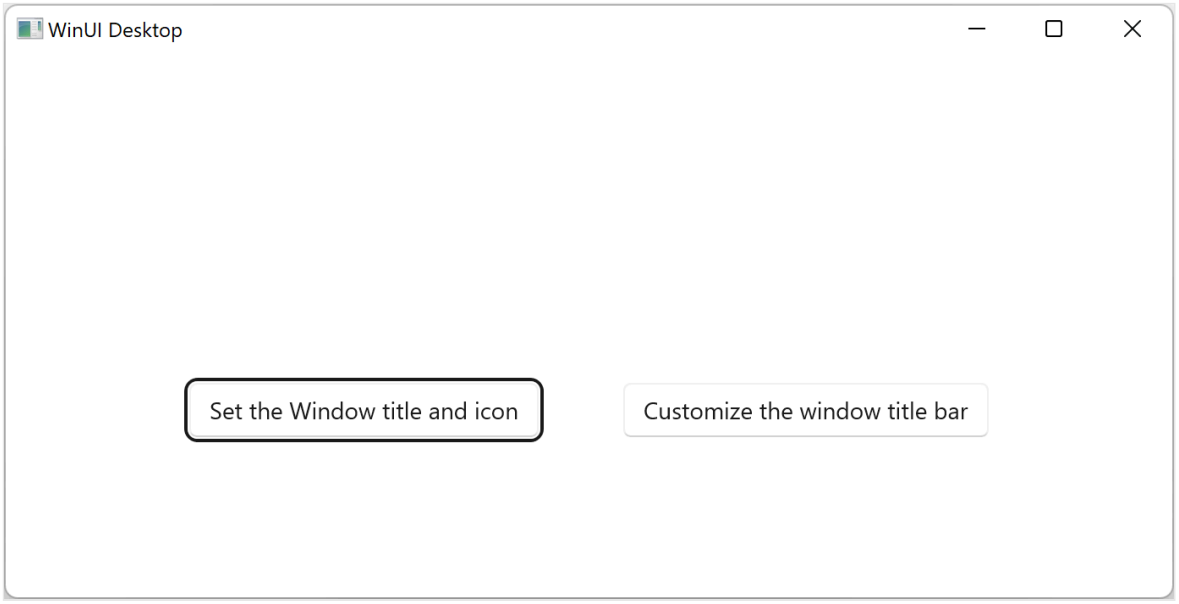
App.xaml

1. In the `App.xaml` file, immediately after the `<!-- Other app resources here -->` comment, we've added some custom-colored brushes for the title bar, as shown below.

C#

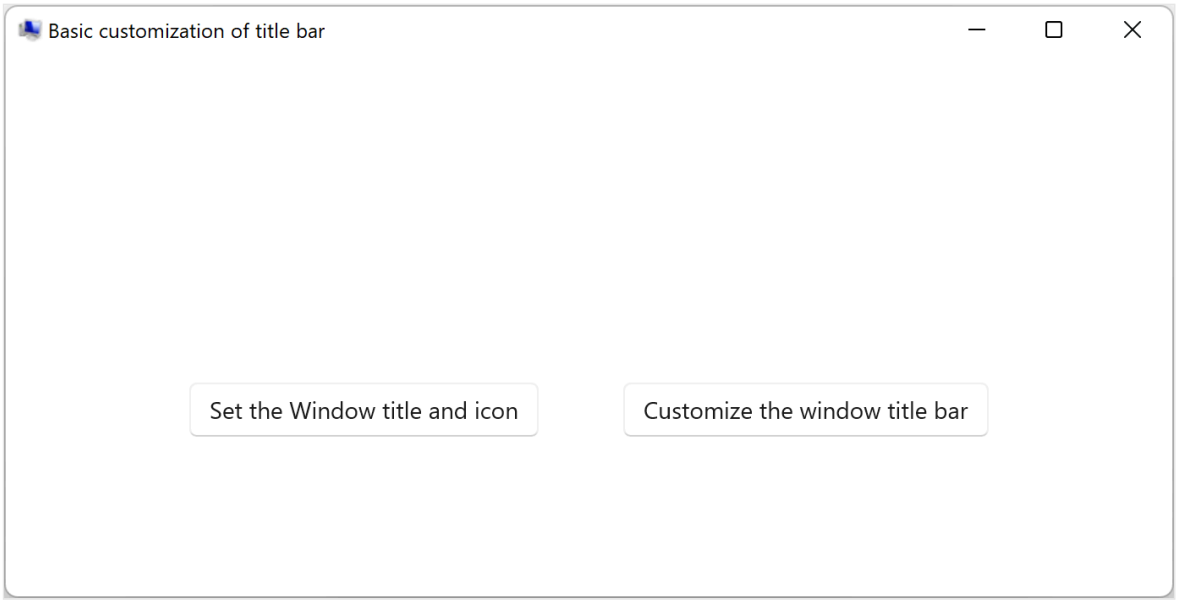
```
<?xml version="1.0" encoding="utf-8"?>
<Application
    x:Class="window_titlebar.App"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:window_titlebar">
    <Application.Resources>
        <ResourceDictionary>
            <ResourceDictionary.MergedDictionaries>
                <XamlControlsResources
xmlns="using:Microsoft.UI.Xaml.Controls" />
                <!-- Other merged dictionaries here -->
            </ResourceDictionary.MergedDictionaries>
            <!-- Other app resources here -->
            <SolidColorBrush
x:Key="WindowCaptionBackground">Green</SolidColorBrush>
            <SolidColorBrush
x:Key="WindowCaptionBackgroundDisabled">LightGreen</SolidColorBrush>
            <SolidColorBrush
x:Key="WindowCaptionForeground">Red</SolidColorBrush>
            <SolidColorBrush
x:Key="WindowCaptionForegroundDisabled">Pink</SolidColorBrush>
        </ResourceDictionary>
    </Application.Resources>
</Application>
```

1. If you've been following along with these steps in your own app, then you can build your project now, and run the app. You'll see an application window similar to the following (with the custom app icon):



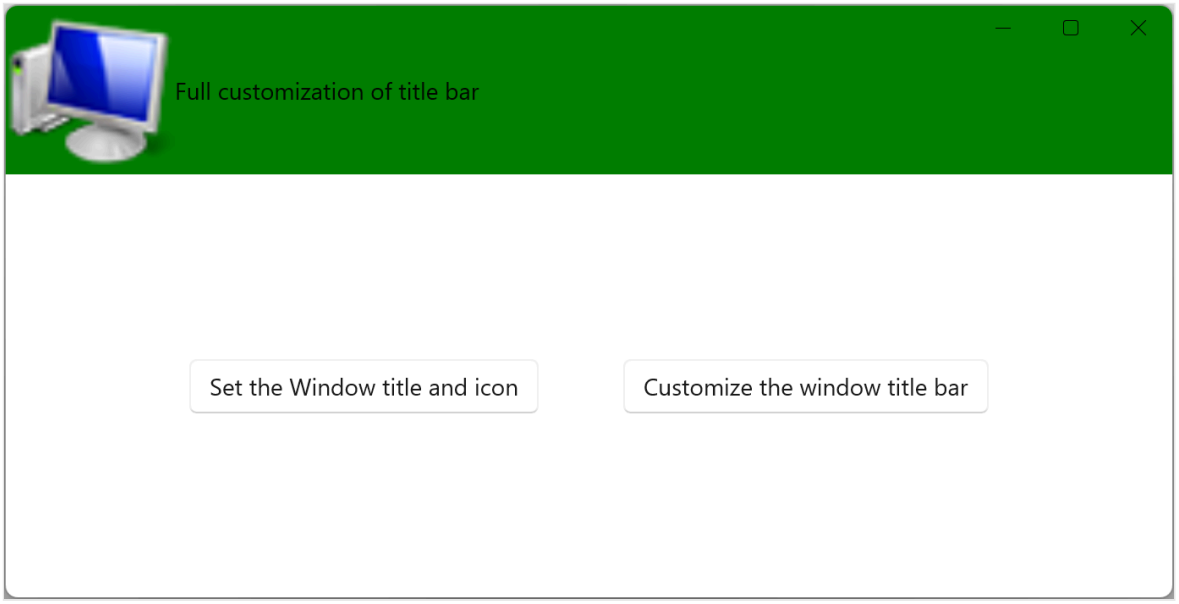
Template app.

- Here's the basic custom title bar:



Template app with custom application icon.

- Here's the fully custom title bar:



Template app with custom title bar.

Build XAML controls with C++/WinRT

Article • 07/09/2024

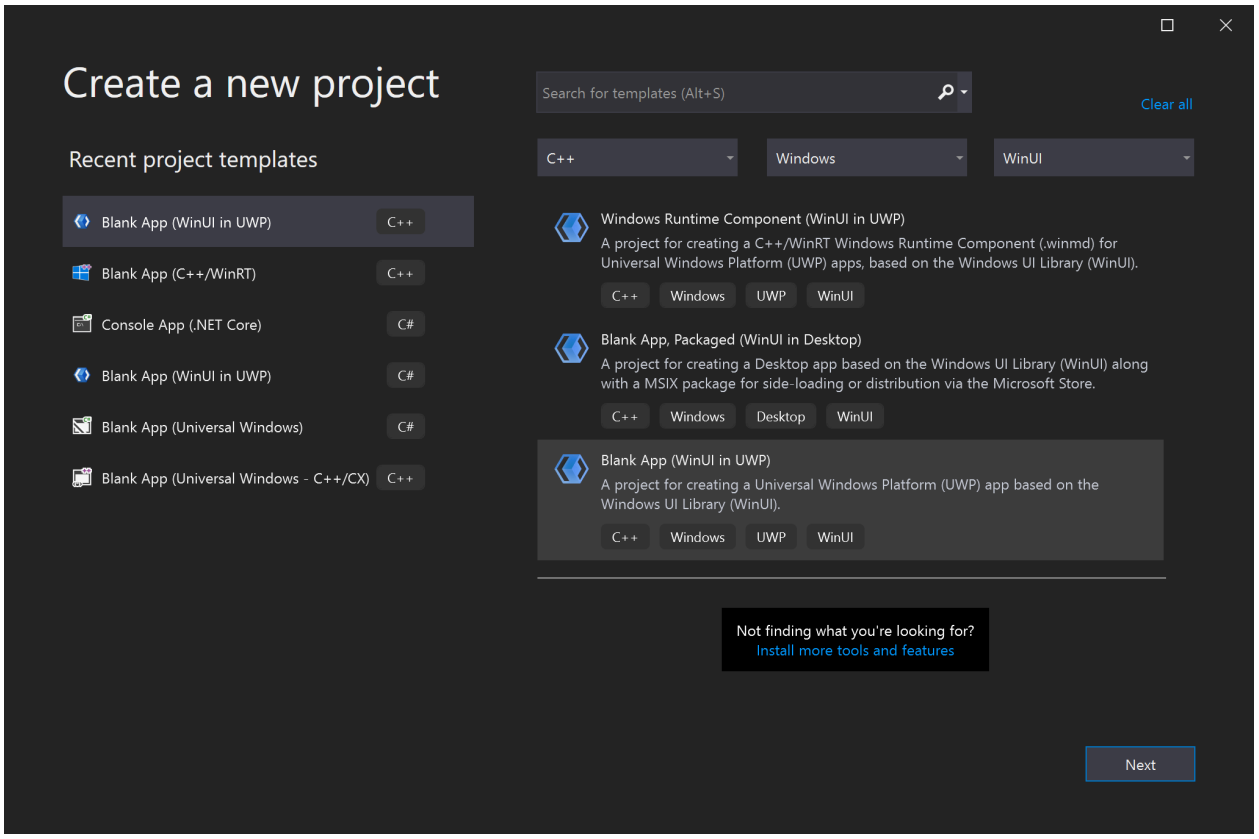
This article walks you through creating a templated XAML control for WinUI 3 with C++/WinRT. Templated controls inherit from **Microsoft.UI.Xaml.Controls.Control** and have visual structure and visual behavior that can be customized using XAML control templates. This article describes the same scenario as the article XAML custom (templated) controls with C++/WinRT but has been adapted to use WinUI 3.

Prerequisites

1. Start developing Windows apps
2. Download and install the latest version of the C++/WinRT Visual Studio Extension (VSIX)

Create a Blank App (BgLabelControlApp)

Begin by creating a new project in Microsoft Visual Studio. In the `Create a new project` dialog, select the **Blank App (WinUI in UWP)** project template, making sure to select the C++ language version. Set the project name to "BgLabelControlApp" so that the file names align with the code in the examples below. Set the **Target version** to Windows 10, version 1903 (build 18362) and **Minimum version** to Windows 10, version 1803 (build 17134). This walkthrough will also work for desktop apps created with the **Blank App, Packaged (WinUI in Desktop)** project template, just make sure to perform all of the steps in the **BgLabelControlApp (Desktop)** project.



Add a templated control to your app

To add a templated control, click the **Project** menu in the toolbar or right-click your project in **Solution Explorer** and select **Add New Item** . Under **Visual C++->WinUI** select the **Custom Control (WinUI)** template. Name the new control "BgLabelControl" and click *Add*. This will add three new files to your project. `BgLabelControl.h` is the header containing the control declarations and `BgLabelControl.cpp` contains the C++/WinRT implementation of the control. `BgLabelControl.idl` is the Interface Definition file that allows the control to be instantiated as a runtime class.

Implement the BgLabelControl custom control class

In the following steps you will update the code in the `BgLabelControl.idl`, `BgLabelControl.h`, and `BgLabelControl.cpp` files in the project directory to implement the runtime class.

The templated control class will be instantiated from XAML markup, and for that reason it's going to be a runtime class. When you build the finished project, the MIDL compiler (midl.exe) will use the `BgLabelControl.idl` file to a generate the Windows Runtime metadata file (.winmd) for your control, which consumers of your component will

reference. For more information on creating runtime classes, see Author APIs with C++/WinRT.

The templated control we are creating will expose a single property which is a string that will be used as a label for the control. Replace the contents of `BgLabelControl.idl` with the following code..

C++/WinRT

```
// BgLabelControl.idl
namespace BgLabelControlApp
{
    runtimeclass BgLabelControl : Microsoft.UI.Xaml.Controls.Control
    {
        BgLabelControl();
        static Microsoft.UI.Xaml.DependencyProperty LabelProperty{ get; };
        String Label;
    }
}
```

The listing above shows the pattern that you follow when declaring a dependency property (DP). There are two pieces to each DP. First, you declare a read-only static property of type DependencyProperty. It has the name of your DP plus Property. You'll use this static property in your implementation. Second, you declare a read-write instance property with the type and name of your DP. If you wish to author an attached property (rather than a DP), then see the code examples in Custom attached properties.

Note that the XAML classes referenced in the code above are in Microsoft.UI.Xaml namespaces. This is what distinguishes them as WinUI controls as opposed to UWP XAML controls, which are defined in Windows.UI.XAML namespaces.

Replace the contents of BgLabelControl.h with the following code.

C++/WinRT

```
// BgLabelControl.h
#pragma once
#include "BgLabelControl.g.h"

namespace winrt::BgLabelControlApp::implementation
{
    struct BgLabelControl : BgLabelControlT<BgLabelControl>
    {
        BgLabelControl() {
DefaultStyleKey(winrt::box_value(L"BgLabelControlApp.BgLabelControl")); }

        winrt::hstring Label()
        {
```

```
            return winrt::unbox_value<winrt::hstring>
(GetValue(m_labelProperty));
        }

        void Label(winrt::hstring const& value)
        {
            SetValue(m_labelProperty, winrt::box_value(value));
        }

        static Microsoft::UI::Xaml::DependencyProperty LabelProperty() {
return m_labelProperty; }

        static void OnLabelChanged(Microsoft::UI::Xaml::DependencyObject
const&, Microsoft::UI::Xaml::DependencyPropertyChangedEventArgs const&);

    private:
        static Microsoft::UI::Xaml::DependencyProperty m_labelProperty;
    };
}
namespace winrt::BgLabelControlApp::factory_implementation
{
    struct BgLabelControl : BgLabelControlT<BgLabelControl,
implementation::BgLabelControl>
    {
    };
}
```

The code shown above implements the **Label** and **LabelProperty** properties, add a static event handler named **OnLabelChanged** to process changes to the value of the dependency property, and adds a private member to store the backing field for **LabelProperty**. Again, note that the XAML classes referenced in the header file are in the Microsoft.UI.Xaml namespaces that belong to the WinUI 3 framework instead of the Windows.UI.Xaml namespaces used by the UWP UI framework.

Next, replace the contents of BgLabelControl.cpp with the following code.

C++/WinRT

```
// BgLabelControl.cpp
#include "pch.h"
#include "BgLabelControl.h"
#if __has_include("BgLabelControl.g.cpp")
#include "BgLabelControl.g.cpp"
#endif

namespace winrt::BgLabelControlApp::implementation
{
    Microsoft::UI::Xaml::DependencyProperty BgLabelControl::m_labelProperty
=
        Microsoft::UI::Xaml::DependencyProperty::Register(
            L"Label",
```

```
            winrt::xaml_typename<winrt::hstring>(),
            winrt::xaml_typename<BgLabelControlApp::BgLabelControl>(),
            Microsoft::UI::Xaml::PropertyMetadata{
winrt::box_value(L"default label"),
Microsoft::UI::Xaml::PropertyChangedCallback{
&BgLabelControl::OnLabelChanged } }
    );

    void
BgLabelControl::OnLabelChanged(Microsoft::UI::Xaml::DependencyObject const&
d, Microsoft::UI::Xaml::DependencyPropertyChangedEventArgs const& /* e */)
    {
        if (BgLabelControlApp::BgLabelControl theControl{
d.try_as<BgLabelControlApp::BgLabelControl>() })
        {
            // Call members of the projected type via theControl.

            BgLabelControlApp::implementation::BgLabelControl* ptr{
winrt::get_self<BgLabelControlApp::implementation::BgLabelControl>
(theControl) };
            // Call members of the implementation type via ptr.
        }
    }
}
```

This walkthrough won't use the **OnLabelChanged** callback, but it's provided so that you can see how to register a dependency property with a property-changed callback. The implementation of **OnLabelChanged** also shows how to obtain a derived projected type from a base projected type (the base projected type is DependencyObject, in this case). And it shows how to then obtain a pointer to the type that implements the projected type. That second operation will naturally only be possible in the project that implements the projected type (that is, the project that implements the runtime class).

The xaml_typename function is provided by the Windows.UI.Xaml.Interop namespace that is not included by default in the WinUI 3 project template. Add a line to the precompiled header file for your project, `pch.h`, to include the header file associated with this namespace.

C++/WinRT

```
// pch.h
...
#include <winrt/Windows.UI.Xaml.Interop.h>
...
```

Define the default style for BgLabelControl

In its constructor, **BgLabelControl** sets a default style key for itself. A templated control needs to have a default style — containing a default control template — which it can use to render itself with in case the consumer of the control doesn't set a style and/or template. In this section we'll add a markup file to the project containing our default style.

Make sure that **Show All Files** is still toggled on (in **Solution Explorer**). Under your project node, create a new folder (not a filter, but a folder) and name it "Themes". Under `Themes`, add a new item of type **Visual C++ > WinUI > Resource Dictionary (WinUI)**, and name it "Generic.xaml". The folder and file names have to be like this in order for the XAML framework to find the default style for a templated control. Delete the default contents of Generic.xaml, and paste in the markup below.

XAML

```
<!-- \Themes\Generic.xaml -->
<ResourceDictionary
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:BgLabelControlApp">

    <Style TargetType="local:BgLabelControl" >
        <Setter Property="Template">
            <Setter.Value>
                <ControlTemplate TargetType="local:BgLabelControl">
                    <Grid Width="100" Height="100" Background="
{TemplateBinding Background}">
                        <TextBlock HorizontalAlignment="Center"
VerticalAlignment="Center" Text="{TemplateBinding Label}"/>
                    </Grid>
                </ControlTemplate>
            </Setter.Value>
        </Setter>
    </Style>
</ResourceDictionary>
```

In this case, the only property that the default style sets is the control template. The template consists of a square (whose background is bound to the **Background** property that all instances of the XAML **Control** type have), and a text element (whose text is bound to the **BgLabelControl::Label** dependency property).

Add an instance of BgLabelControl to the main UI page

Open `MainWindow.xaml`, which contains the XAML markup for our main UI page. Immediately after the **Button** element (inside the **StackPanel**), add the following markup.

XAML

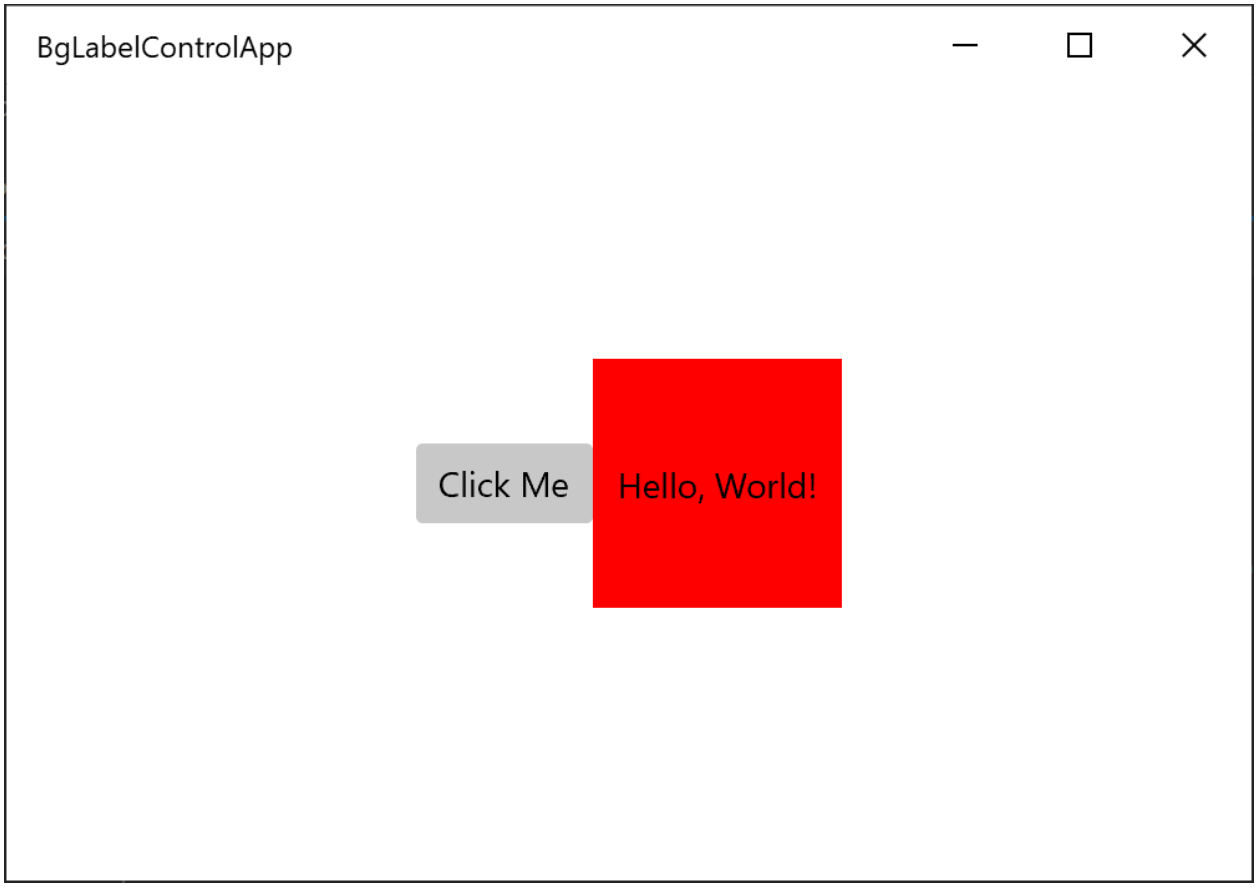
```
<local:BgLabelControl Background="Red" Label="Hello, World!"/>
```

Also, add the following include directive to `MainWindow.h` so that the **MainWindow** type (a combination of compiling XAML markup and imperative code) is aware of the **BgLabelControl** templated control type. If you want to use **BgLabelControl** from another XAML page, then add this same include directive to the header file for that page, too. Or, alternatively, just put a single include directive in your precompiled header file.

C++/WinRT

```
//MainWindow.h
...
#include "BgLabelControl.h"
...
```

Now build and run the project. You'll see that the default control template is binding to the background brush, and to the label, of the **BgLabelControl** instance in the markup.



Implementing overridable functions, such as MeasureOverride and OnApplyTemplate

You derive a templated control from the **Control** runtime class, which itself further derives from base runtime classes. And there are overridable methods of **Control**, **FrameworkElement**, and **UIElement** that you can override in your derived class. Here's a code example showing you how to do that.

C++/WinRT

```
// Control overrides.
void OnPointerPressed(Microsoft::UI::Xaml::Input::PointerRoutedEventArgs
const& /* e */) const { ... };

// FrameworkElement overrides.
Windows::Foundation::Size MeasureOverride(Windows::Foundation::Size const&
/* availableSize */) const { ... };
void OnApplyTemplate() const { ... };

// UIElement overrides.
Microsoft::UI::Xaml::Automation::Peers::AutomationPeer
OnCreateAutomationPeer() const { ... };
```

Overridable functions present themselves differently in different language projections. In C#, for example, overridable functions typically appear as protected virtual functions. In C++/WinRT, they're neither virtual nor protected, but you can still override them and provide your own implementation, as shown above.

Generating the control source files without using a template.

This section shows how you can generate the necessary source files for creating your custom control without using the **Custom Control** item template.

First, add a new Midl File (.idl) item to the project. From the **Project** menu, select **Add New Item...** and type "MIDL" in the search box to find the .idl file item. Name the new file `BgLabelControl.idl` so that the name will be consistent with the steps in this article. Delete the default contents of `BgLabelControl.idl`, and paste in the runtime class declaration shown in the steps above.

After saving the new .idl file, the next step is to generate the Windows Runtime metadata file (.winmd) and stubs for the .cpp and .h implementation files that you will use to implement the templated control. Generate these files by building the solution,

which will cause the MIDL compiler (midl.exe) to compile the .idl file you created. Note that the Solution will not build successfully and Visual Studio will show build errors in the output window, but the necessary files will be generated.

Copy the stub files BgLabelControl.h and BgLabelControl.cpp from \BgLabelControlApp\BgLabelControlApp\Generated Files\sources\ into the project folder. In **Solution Explorer**, make sure Show All Files is toggled on. Right-click the stub files that you copied, and click **Include In Project**.

The compiler places a static_assert line at the top of BgLabelControl.h and BgLabelControl.cpp to prevent the generated files from being compiled. When implementing your control, you should remove these lines from the files you have placed in your project directory. For this walkthrough, you can just overwrite the entire contents of the files with the code provided above.

Build XAML controls with C#

Article • 07/12/2024

This article walks you through creating a templated XAML control for WinUI 3 with C#. Templated controls inherit from **Microsoft.UI.Xaml.Controls.Control** and have visual structure and visual behavior that can be customized using XAML control templates.

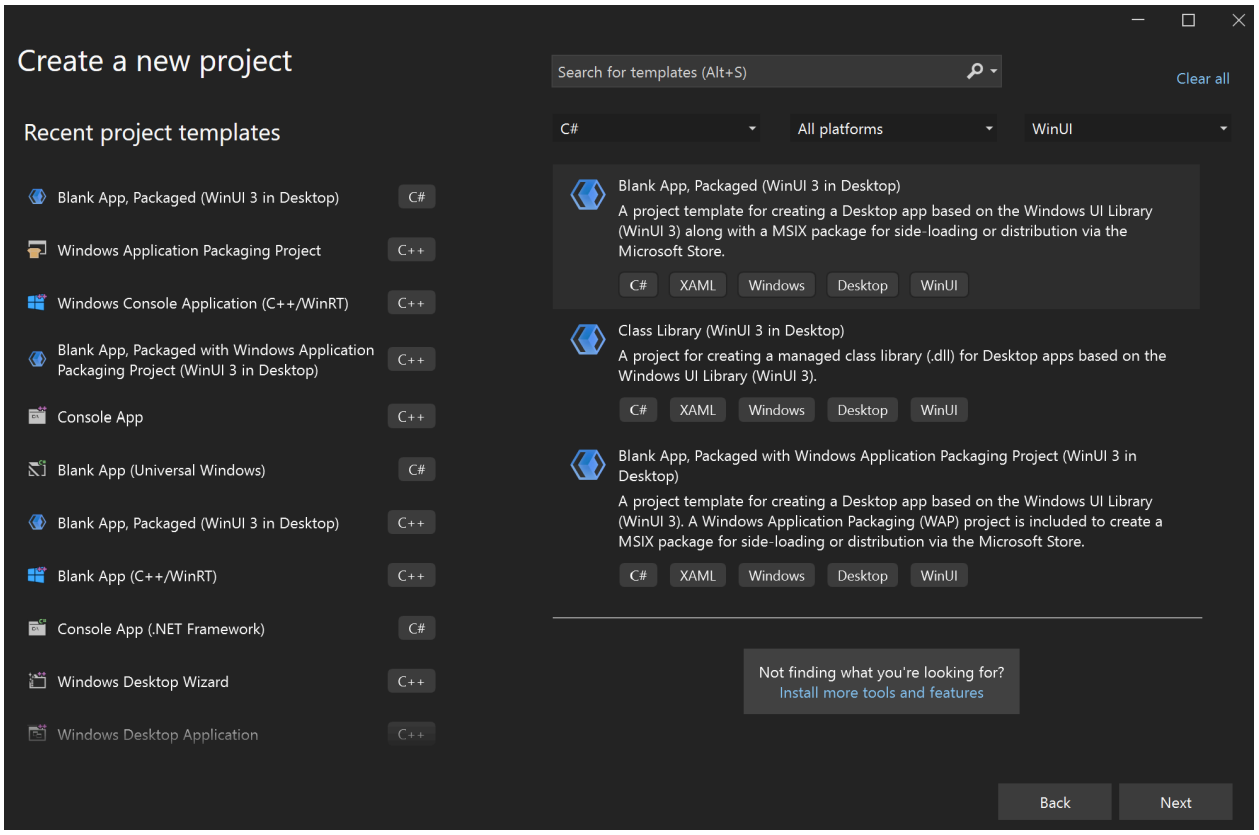
To create standalone WinUI 3 components in C# for consumption from both C# and C++/WinRT apps, see the article Walkthrough: Create a C# component with WinUI 3 controls, and consume it from a C++ Windows App SDK application.

Prerequisites

1. Set up your development environment—see Install tools for the Windows App SDK.
2. Follow the instructions on how to Create your first WinUI 3 project.

Create a Blank App (BgLabelControlApp)

Begin by creating a new project in Microsoft Visual Studio. In the **Create a new project** dialog, select the **Blank App, Packaged (WinUI 3 in Desktop)** project template, making sure to select the C# language version. Set the project name to "BgLabelControlApp" so that the file names align with the code in the examples below.



Add a templated control to your app

To add a templated control, click the **Project** menu in the toolbar or right-click your project in **Solution Explorer** and select **Add New Item** . Under **Visual C#->WinUI** select the **Custom Control (WinUI 3)** template. Name the new control "BgLabelControl" and click *Add*.

Update the custom control C# file

In the C# file, BgLabelControl.cs, note that the constructor defines the **DefaultStyleKey** property for our control. This key identifies the default template that will be used if the consumer of the control doesn't explicitly specify a template. The key value is the *type* of our control. We will see this key in use later when we implement our generic template file.

C#

```
public BgLabelControl()
{
    this.DefaultStyleKey = typeof(BgLabelControl);
}
```

Our templated control will have a text label that can be set programmatically in code, in XAML, or via data binding. In order for the system to keep the text of our control's label

up to date, it needs to be implemented as a DependencyPropety. To do this, first we declare a string property and call it **Label**. Instead of using a backing variable, we set and get the value of our dependency property by calling GetValue and SetValue. These methods are provided by the DependencyObject, which **Microsoft.UI.Xaml.Controls.Control** inherits.

C#

```
public string Label
{
    get => (string)GetValue(LabelProperty);
    set => SetValue(LabelProperty, value);
}
```

Next, declare the dependency property and register it with the system by calling DependencyProperty.Register. This method specifies the name and type of our **Label** property, the type of the owner of the property, our **BgLabelControl** class, and the default value for the property.

C#

```
DependencyProperty LabelProperty = DependencyProperty.Register(
    nameof(Label),
    typeof(string),
    typeof(BgLabelControl),
    new PropertyMetadata(default(string), new
PropertyChangedCallback(OnLabelChanged)));
```

These two steps are all that's required to implement a dependency property, but for this example, we'll add an optional handler for the **OnLabelChanged** event. This event is raised by the system whenever the property value is updated. In this case we check to see if the new label text is an empty string or not and update a class variable accordingly.

C#

```
public bool HasLabelValue { get; set; }

private static void OnLabelChanged(DependencyObject d,
DependencyPropertyChangedEventArgs e)
{
    BgLabelControl labelControl = d as BgLabelControl; //null checks omitted
    String s = e.NewValue as String; //null checks omitted
    if (s == String.Empty)
    {
        labelControl.HasLabelValue = false;
    }
```

```
    else
    {
        labelControl.HasLabelValue = true;
    }
}
```

For more information on how dependency properties work, see Dependency properties overview.

Define the default style for BgLabelControl

A templated control must provide a default style template that is used if the user of the control doesn't explicitly set a style. In this step, we will modify the generic template file for our control.

The generic template file is generated when you add the **Custom Control (WinUI)** to your app. The file is named "Generic.xaml" and is generated in the **Themes** folder in solution explorer. The folder and file names are required in order for the XAML framework to find the default style for a templated control. Delete the default contents of Generic.xaml, and paste in the markup below.

XAML

```
<!-- \Themes\Generic.xaml -->
<ResourceDictionary
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:BgLabelControlApp">

    <Style TargetType="local:BgLabelControl" >
        <Setter Property="Template">
            <Setter.Value>
                <ControlTemplate TargetType="local:BgLabelControl">
                    <Grid Width="100" Height="100" Background="
{TemplateBinding Background}">
                        <TextBlock HorizontalAlignment="Center"
VerticalAlignment="Center" Text="{TemplateBinding Label}"/>
                    </Grid>
                </ControlTemplate>
            </Setter.Value>
        </Setter>
    </Style>
</ResourceDictionary>
```

In this example you can see that the **TargetType** attribute of the **Style** element is set to our **BgLabelControl** type within the **BgLabelControlApp** namespace. This type is the

same value as we specified above for the **DefaultStyleKey** property in the control's constructor which identifies this as the default style for the control.

The **Text** property of the **TextBlock** in the control template is bound to our control's **Label** dependency property. The property is bound using the TemplateBinding markup extension. This example also binds the **Grid** background to the **Background** dependency property which is inherited from the **Control** class.

Add an instance of BgLabelControl to the main UI page

Open `MainWindow.xaml`, which contains the XAML markup for our main UI page. Immediately after the **Button** element (inside the **StackPanel**), add the following markup.

XAML

```
<local:BgLabelControl Background="Red" Label="Hello, World!"/>
```

Build and run the app and you will see the templated control, with the background color and label we specified.

Localize your WinUI 3 app

Article • 10/24/2022

For more info about the value proposition of localizing your app, see Globalization and localization.

To support multiple languages in a WinUI desktop app, and ensure proper localization of your packaged project, add the appropriate resources to the project (see App resources and the Resource Management System) and declare each supported language in the **package.appxmanifest** file of your project. When you build the project, the specified languages are added to the generated app manifest (**AppxManifest.xml**) and the corresponding resources are used.

> **Note**
>
> As an unpackaged WinUI 3 app (see Create your first WinUI 3 project) doesn't contain a `package.appxmanifest` file, no further action is needed after adding the appropriate resources to the project.

1. Open the .wapproj's `package.appxmanifest` in a text editor and locate the following section:

   XML

   ```
   <Resources>
       <Resource Language="x-generate"/>
   </Resources>
   ```

2. Replace the `<Resource Language="x-generate">` with `<Resource />` elements for each of your supported languages. For example, the following markup specifies that "en-US" and "es-ES" localized resources are available:

   XML

   ```
   <Resources>
       <Resource Language="en-US"/>
       <Resource Language="es-ES"/>
   </Resources>
   ```

Test apps built with the Windows App SDK and WinUI

Article • 05/31/2024

In this topic we provide some recommendations for how to test and validate functionality in apps created with the Windows App SDK using Windows UI Library (WinUI) user interface (UI) features.

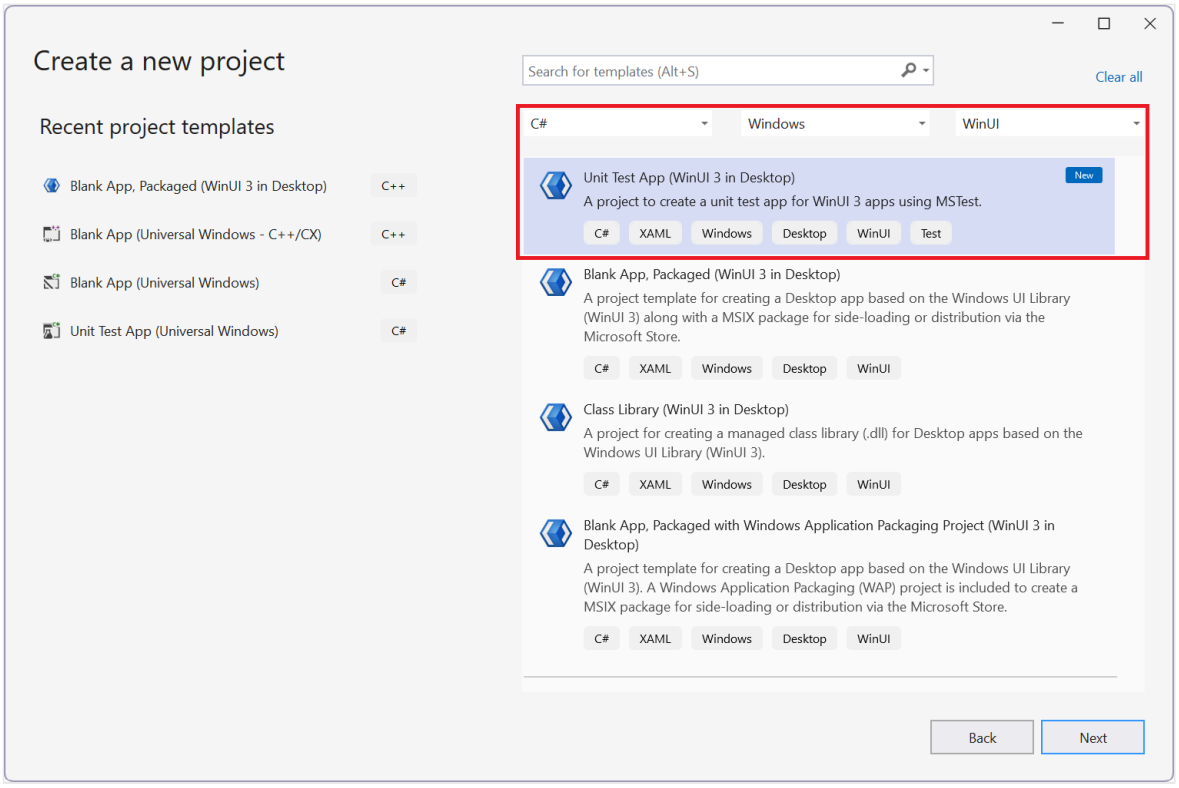
How do I test WinUI functionality in my app?

Most object types under the Microsoft.UI.Xaml namespaces must be used from a UI thread in a Xaml application process. (For details on testing apps created with Windows App SDK that don't use WinUI, see the following section, How do I test non-WinUI functionality in my app?.)

The following steps describe how to use Visual Studio to test code that depends on Microsoft.UI.Xaml types and executes in the context of a Xaml application:

1. Create a unit test project in the same solution as the app you want to test. (This uses MSTest to execute the test code and will initialize a Xaml Window and a Xaml UI Thread.)

   Right click your solution in Solution Explorer, select **Add -> New Project** from the context menu, and choose **Unit Test App (WinUI 3 in Desktop)** for C# or **Unit Test App (WinUI 3)** for C++.



2. Mark your test methods with the `[UITestMethod]` attribute instead of the standard `[TestMethod]` attribute to ensure they execute on the UI thread.

> **Note**
>
> We recommend that you refactor any code to be tested by pulling it out of the main app project and placing it into a library project. Both your app project and your unit test project can then reference that library project.

See Unit tests for Windows UI Library (WinUI) apps in Visual Studio for an example of using this test project.

How do I test non-WinUI functionality in my app?

In many cases, an app includes functionality that does not depend on Microsoft.UI.Xaml types but still needs testing. Various tools are available for testing .NET code, including MSTest, NUnit and xUnit. For more details on testing .NET apps, see Testing in .NET.

In Visual Studio, you can create a new project for any of these testing tools by right clicking your solution in Solution Explorer, selecting **Add -> New Project** from the context menu, choosing **C#** from the **All languages** selector/**Windows** from the **All languages** selector/**Test** from the **All project types** selector, and then picking the

appropriate testing tool from the list (**MSTest Test Project**, **NUnit Test Project** or **xUnit Test Project**).

When creating a new MSTest, NUnit or xUnit project that references a WinUI project, you must:

1. Update the `TargetFramework` in the .csproj file of your testing project. This value must match the `TargetFramework` in the WinUI project (). By default MSTest, NUnit and xUnit projects target the full range of platforms supported by .NET, but a WinUI project only supports Windows and has a more specific TargetFramework.

   For example, if targeting .NET 8, update the TargetFramework of the unit test project from `<TargetFramework>net8.0</TargetFramework>` to `<TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>`.

2. Update the RuntimeIdentifiers in your test project.

   ```
   <RuntimeIdentifiers
   Condition="$([MSBuild]::GetTargetFrameworkVersion('$(TargetFramework)')) &gt;=
   8">win-x86;win-x64;win-arm64</RuntimeIdentifiers>
   ```

   ```
   <RuntimeIdentifiers
   Condition="$([MSBuild]::GetTargetFrameworkVersion('$(TargetFramework)')) &lt;
   8">win10-x86;win10-x64;win10-arm64</RuntimeIdentifiers>
   ```

3. Add the following property to the `PropertyGroup` in .csproj file of your test project to ensure that the test loads the WinAppSDK runtime:
   `<WindowsAppSdkBootstrapInitialize>true</WindowsAppSdkBootstrapInitialize>`

4. Ensure that the Windows App SDK runtime is installed on the machine running the test. For more information on Windows App SDK deployment, see Windows App SDK deployment guide for framework-dependent apps packaged with external location (or unpackaged).

Unit tests for Windows UI Library (WinUI) apps in Visual Studio

Article • 05/31/2024

This article describes how to create unit tests for WinUI apps in Visual Studio using the built-in unit test project templates.

For a general overview of testing Windows App SDK apps, see Test apps built with the Windows App SDK and WinUI 3.

> **Note**
>
> The unit test app described here is written in the context of a WinUI application. This is required for any tests that execute code requiring the Xaml runtime. This project will create a Xaml UI Thread and execute the tests.

In this tutorial, you learn how to:

- ✓ Create a **Unit Test App (WinUI 3 in Desktop)** for C# or **Unit Test App (WinUI 3)** for C++ project in Visual Studio.
- ✓ Use the Visual Studio **Text Explorer**.
- ✓ Add a **Class Library (WinUI 3 in Desktop)** project for testing.
- ✓ Run tests with the Visual Studio Test Explorer.

Prerequisites

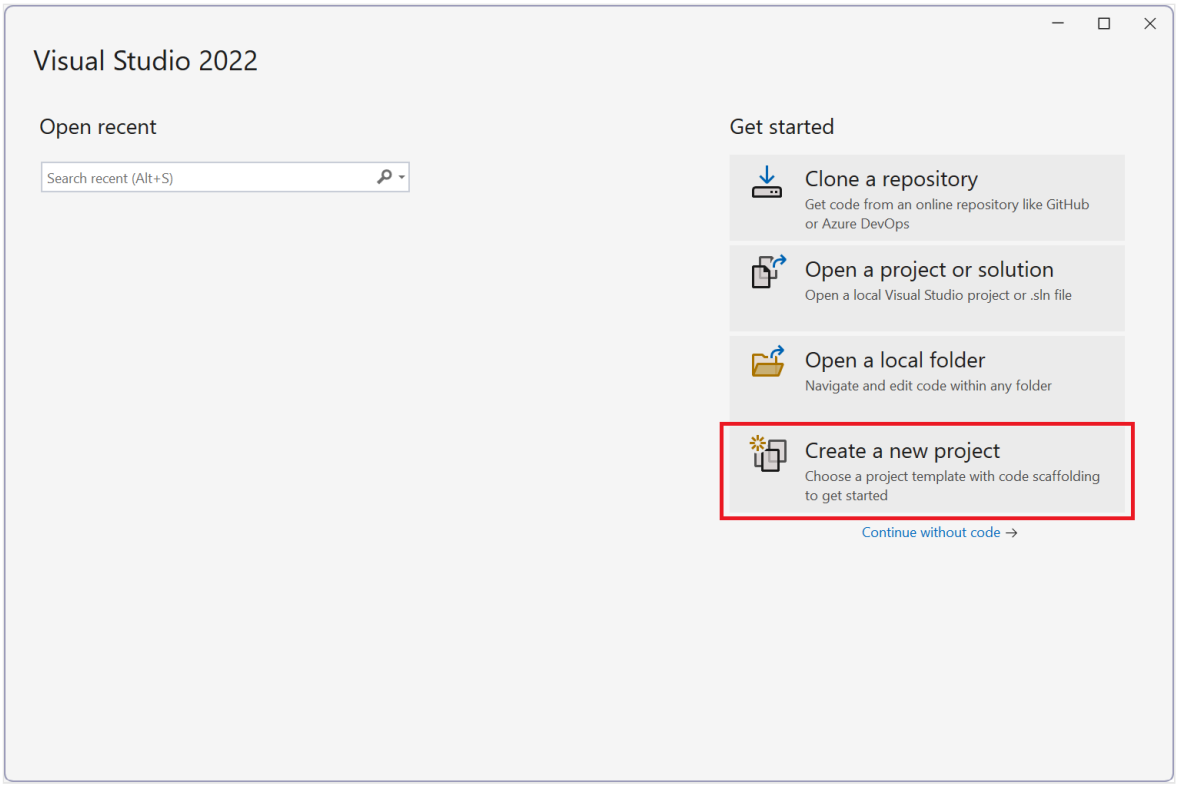
You must have Visual Studio installed.

If you haven't already installed Visual Studio, go to the Visual Studio downloads page to install it for free.

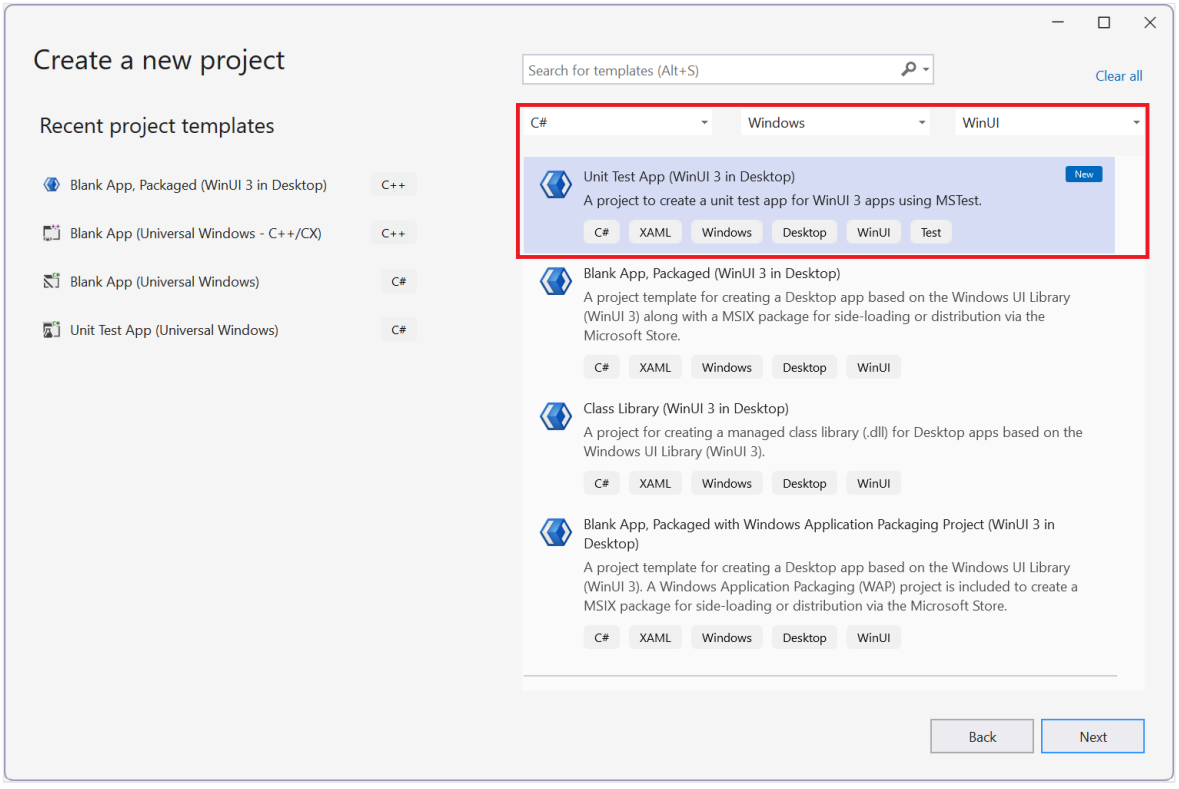
How do I create a Test App (WinUI 3 in Desktop) project

To start, create a unit test project. The project type comes with all the template files you need.

1. Open Visual Studio and select **Create a new project** in the Start window.



2. In the **Create a new project** window, filter projects to **C#**, **Windows**, and **WinUI**, select the **Unit Test App in Desktop (WinUI 3)** template (or **Unit Test App (WinUI 3)** for C++), and then select **Next**



3. [Optional] On the **Configure your new project** window, change the **Project name**, **Solution name** (uncheck **Place solution and project in the same directory**) and the **Location** of your project.

4. Select **Create**.

How do I run tests with Test Explorer

When you create the test project, your tests appear in **Test Explorer**, which is used to run your unit tests. You can also group tests into categories, filter the test list, create, save, and run playlists of tests, debug unit tests and (in Visual Studio Enterprise) analyze code coverage.

The UnitTests.cs file contains the source code for the unit tests used by **Test Explorer**. By default, the basic sample tests shown here are created automatically:

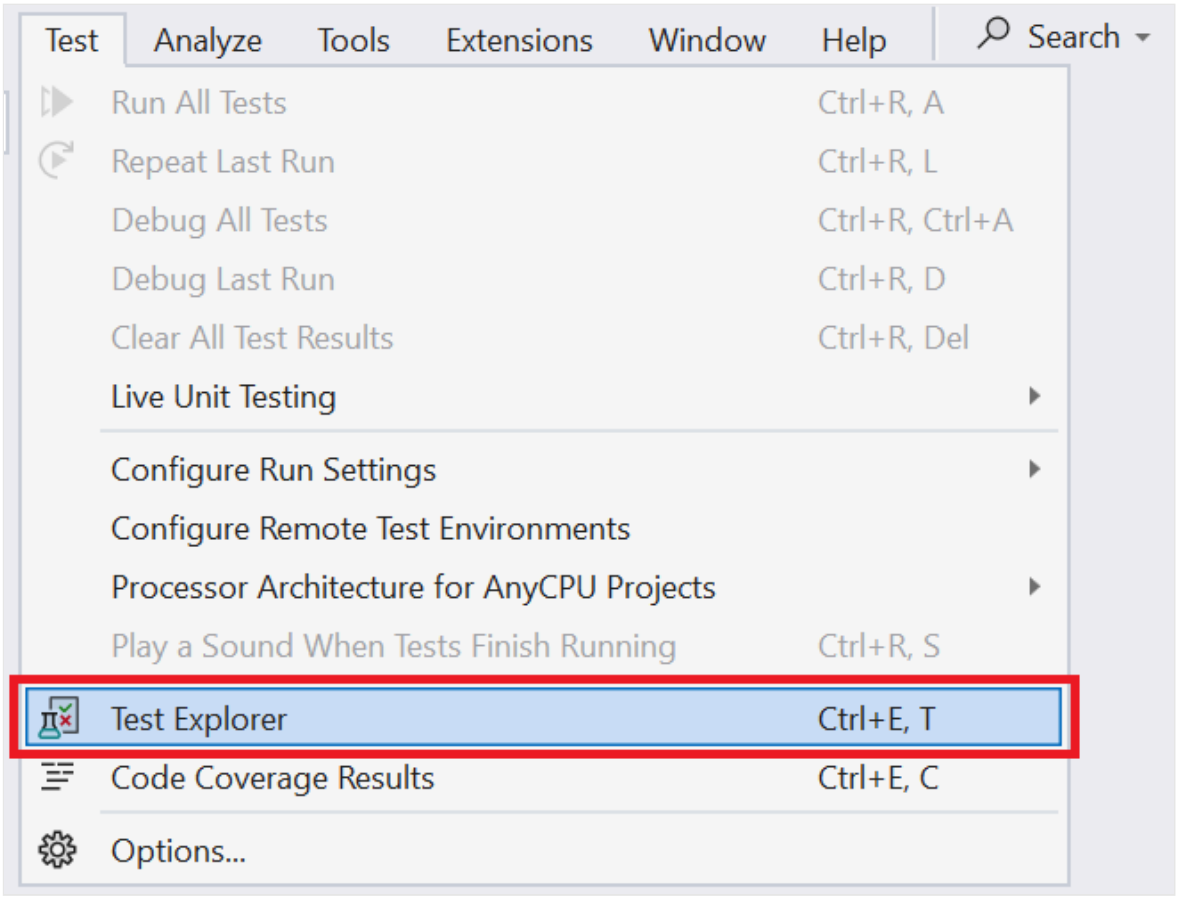
C#

```
namespace WinUITest1
{
   [TestClass]
   public class UnitTest1
   {
      [TestMethod]
      public void TestMethod1()
      {
         Assert.AreEqual(0, 0);
      }

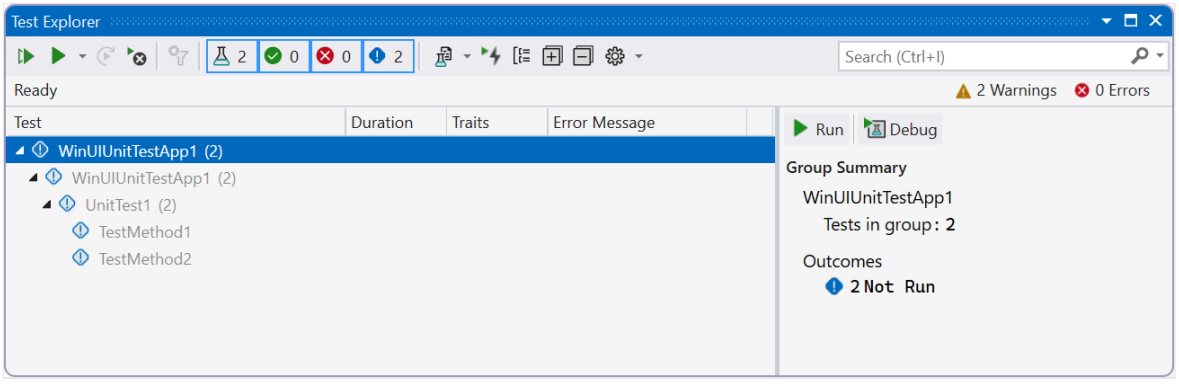
      // Use the UITestMethod attribute for tests that need to run on the UI
thread.
      [UITestMethod]
      public void TestMethod2()
      {
         var grid = new Grid();
         Assert.AreEqual(0, grid.MinWidth);
      }
   }
}
```

1. If you haven't done so already, build your solution. This will allow Visual Studio to "discover" all available tests.

2. Open Test Explorer. If it's not visible, open the **Test** menu, and then choose **Test Explorer** (or press **Ctrl** + **E, T**).

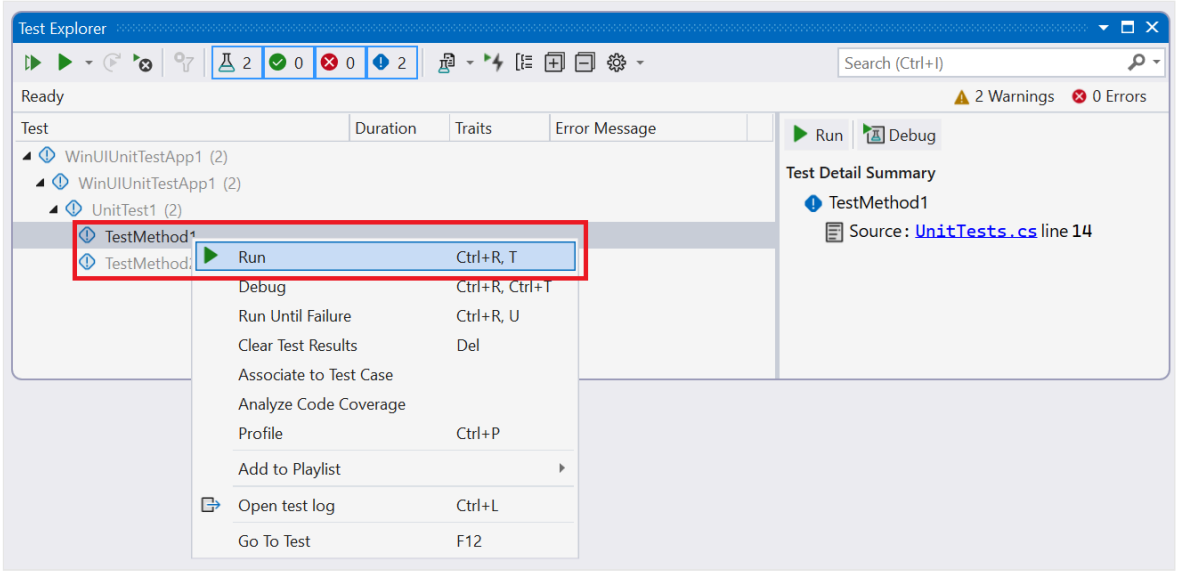


3. View tests. In the **Test Explorer** window, expand all nodes (only the sample tests will be present at this point).

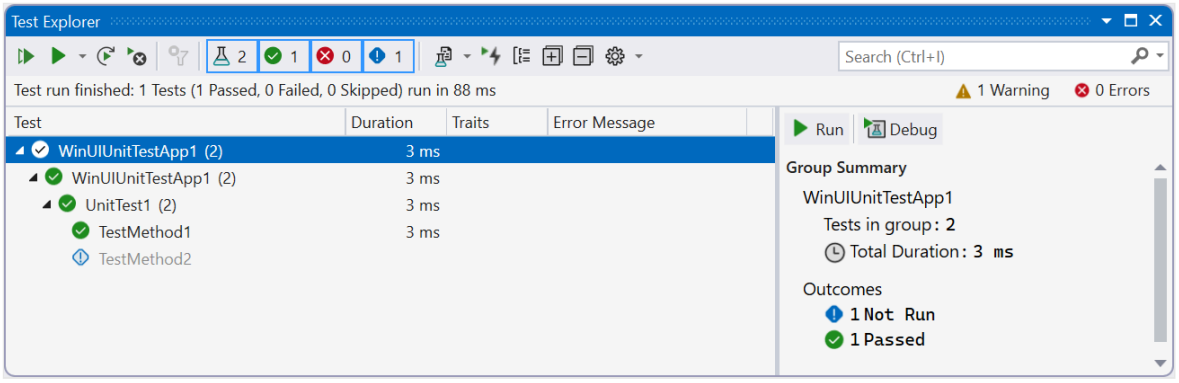


4. Run tests.

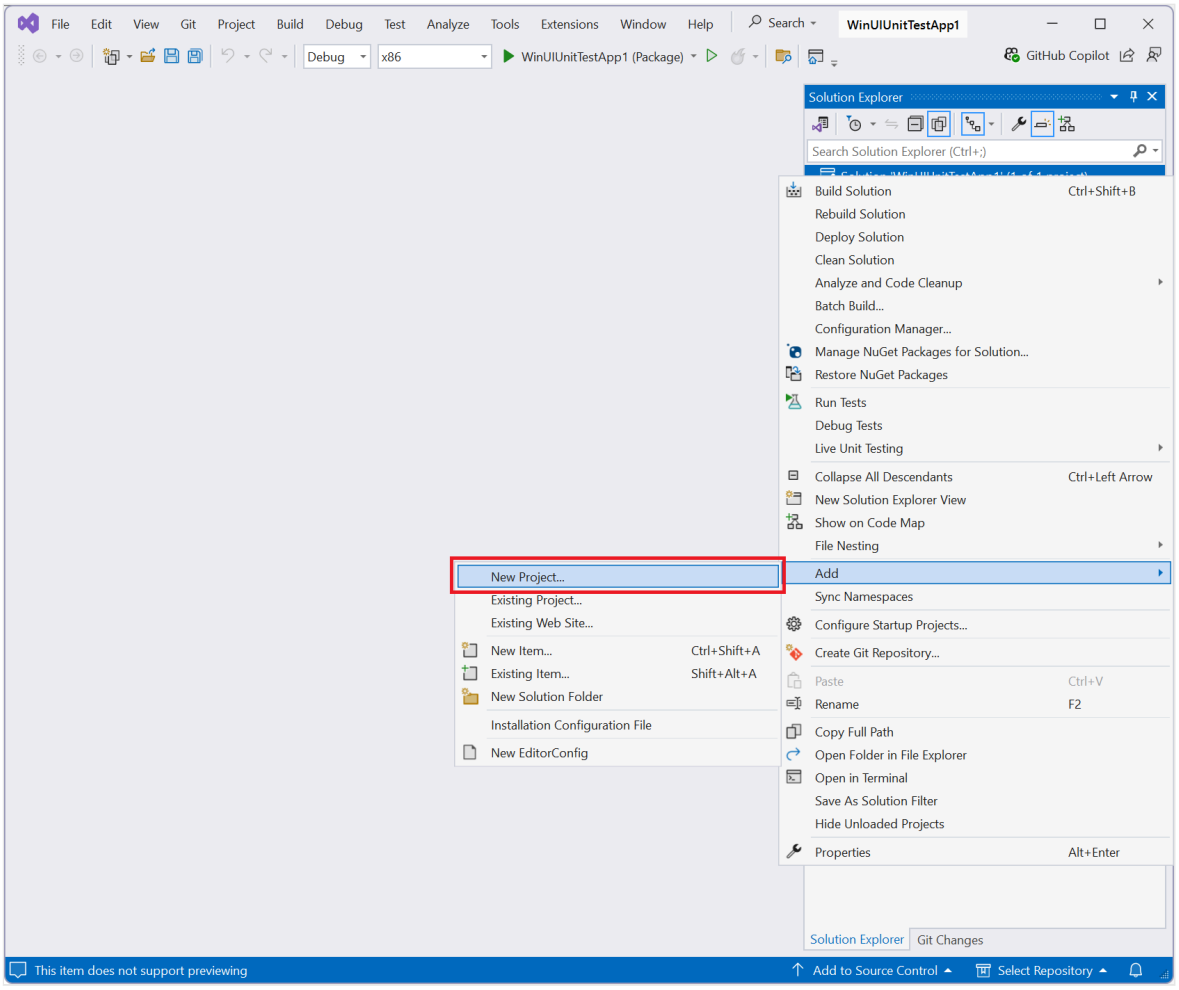
   - Right click on individual test nodes and select **Run**.
   - Select a test and either press the **Play** button or press **Ctrl + R, T**.
   - Press the **Run All Tests In View** button or press **Ctrl + R, V**.



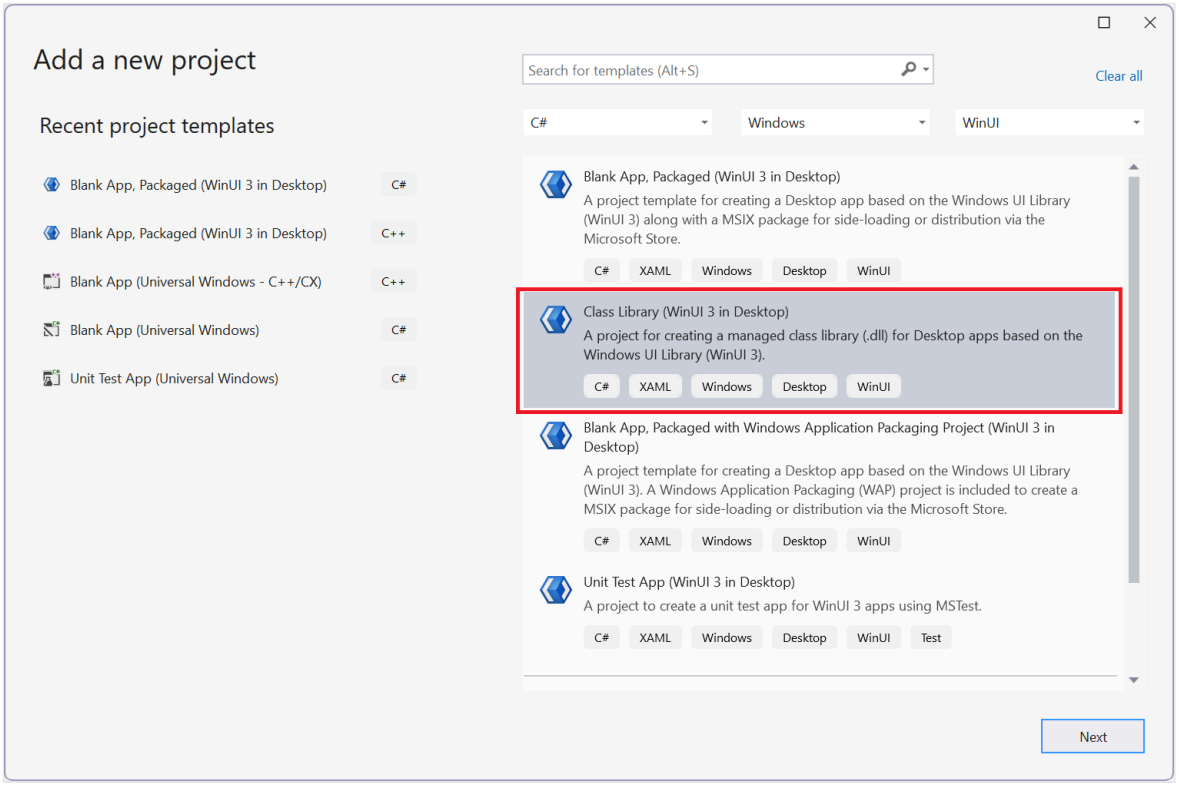
5. Review results. After tests are complete, results are shown in the **Test Explorer** window.



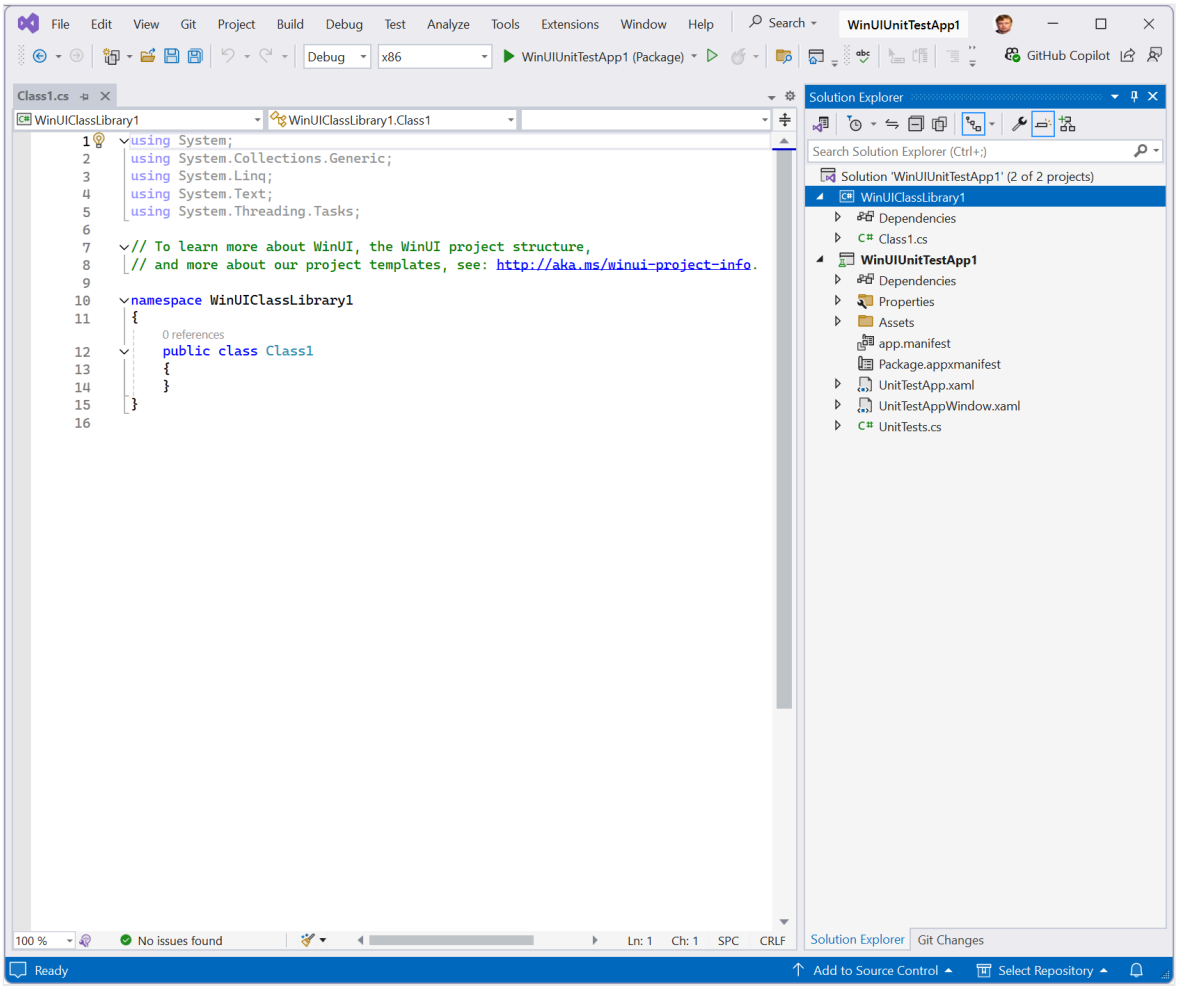
6. Add a new project to the unit test solution. In the Solution Explorer, right click the solution and select **Add -> New Project...**.



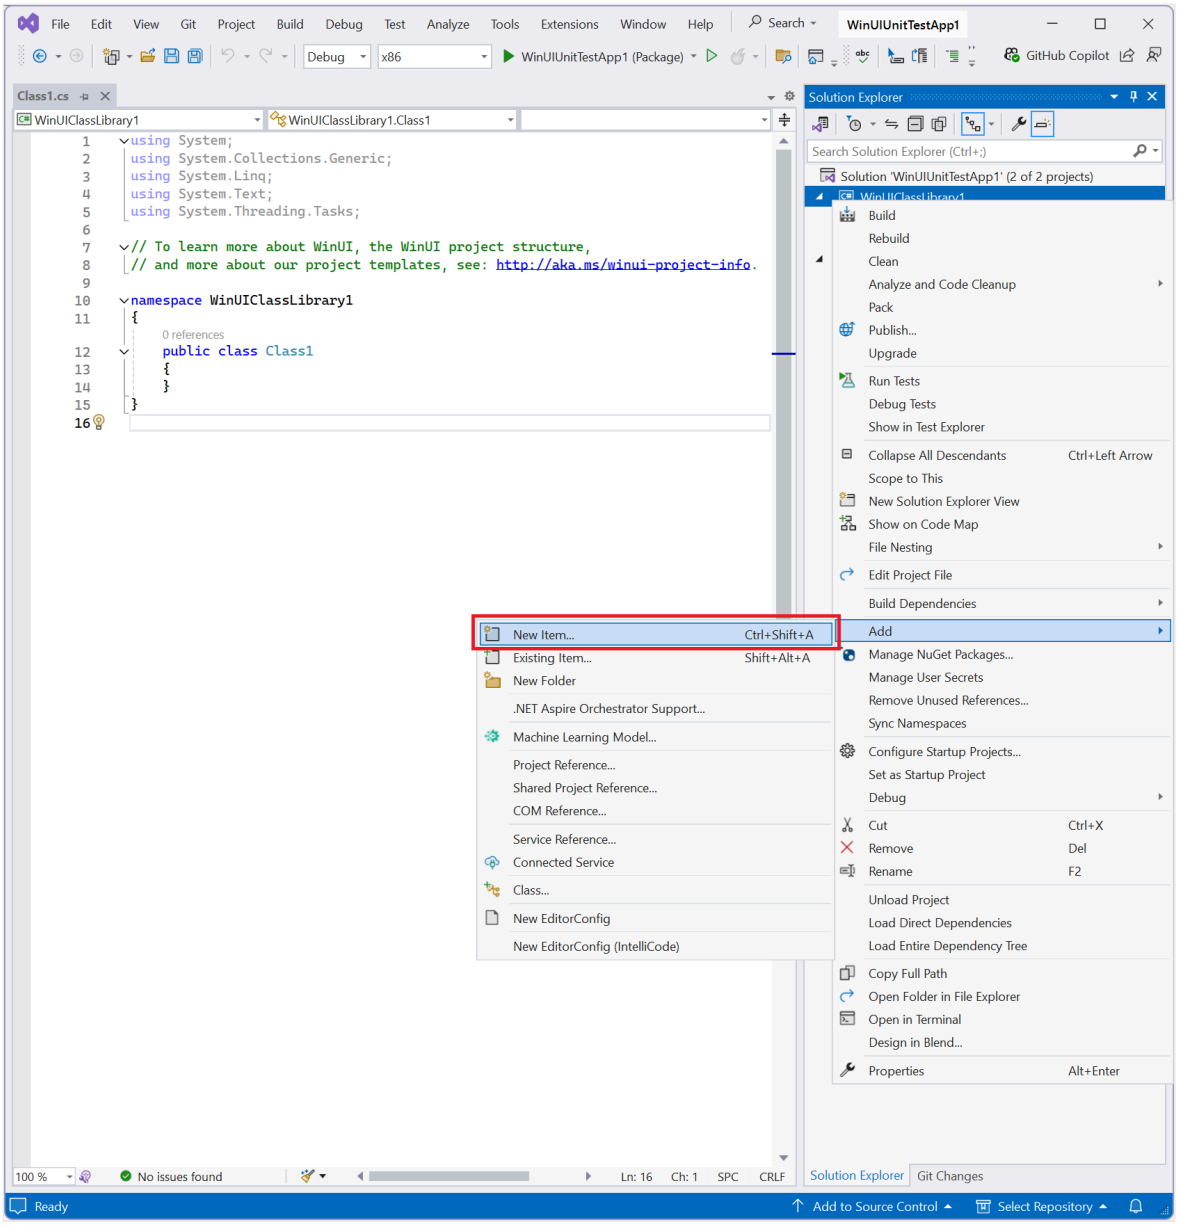
7. For this example, add a WinUI class library project. From the New Project window, filter on C#/Windows/WinUI and select **Class Library (WinUI 3 in Desktop)**.



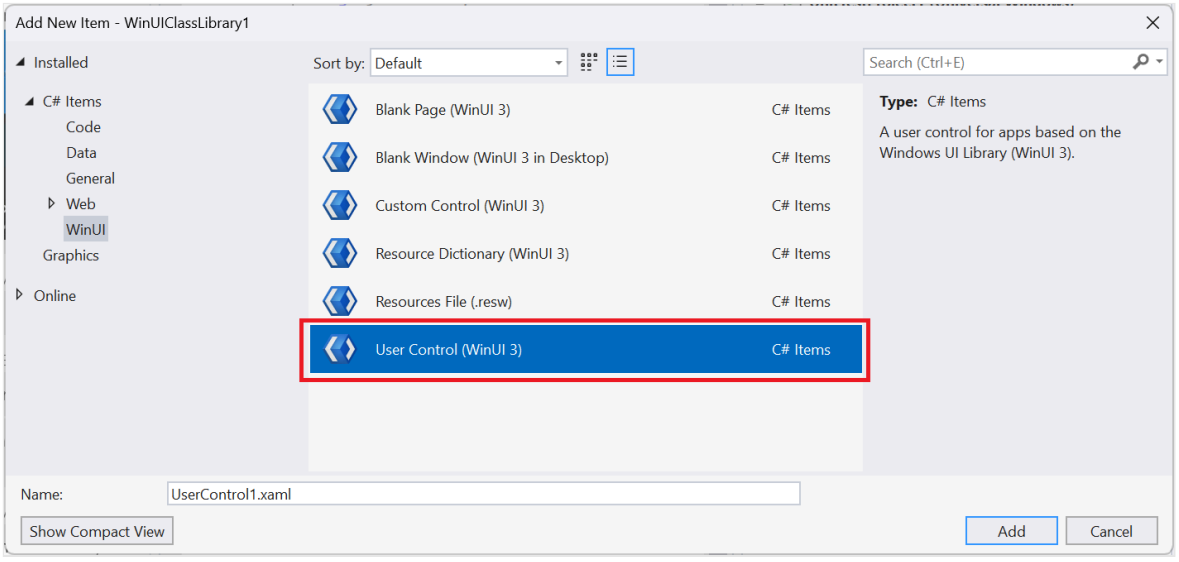
8. Select Next and enter a name for the project (for this example we use "WinUIClassLibrary1") and press **Create**.



9. Add a new UserControl to the project. In the Solution Explorer, right click on the WinUI class library project you just added and select **Add** -> **New Item** from the context menu.



10. In the **Add New Item** window, select the **WinUI** node in the **Installed** items list and then choose **User Control (WinUI 3)** from the results. Name the control "UserControl1".



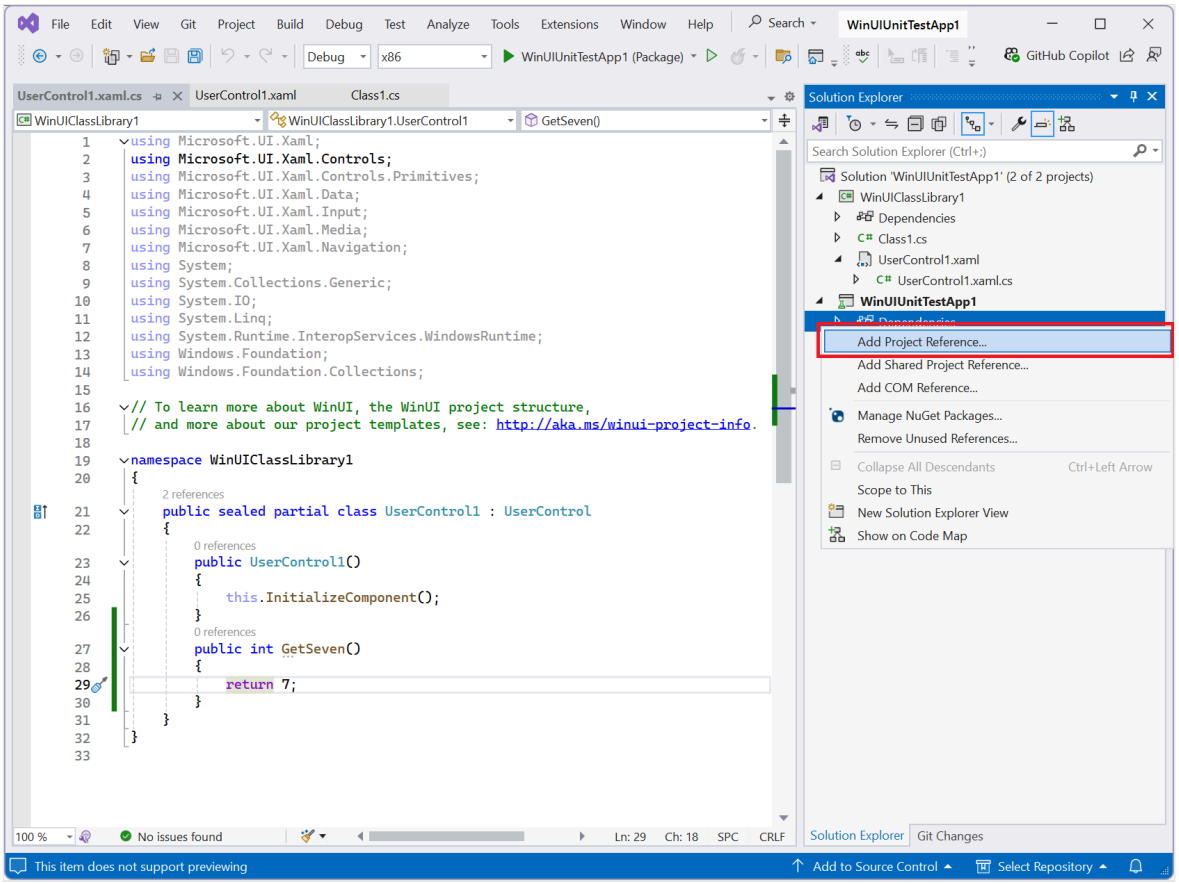
11. Open the UserControl1.xaml.cs code-behind file. For this example, we add a new public method called "GetSeven()" that simply returns an integer.

C#

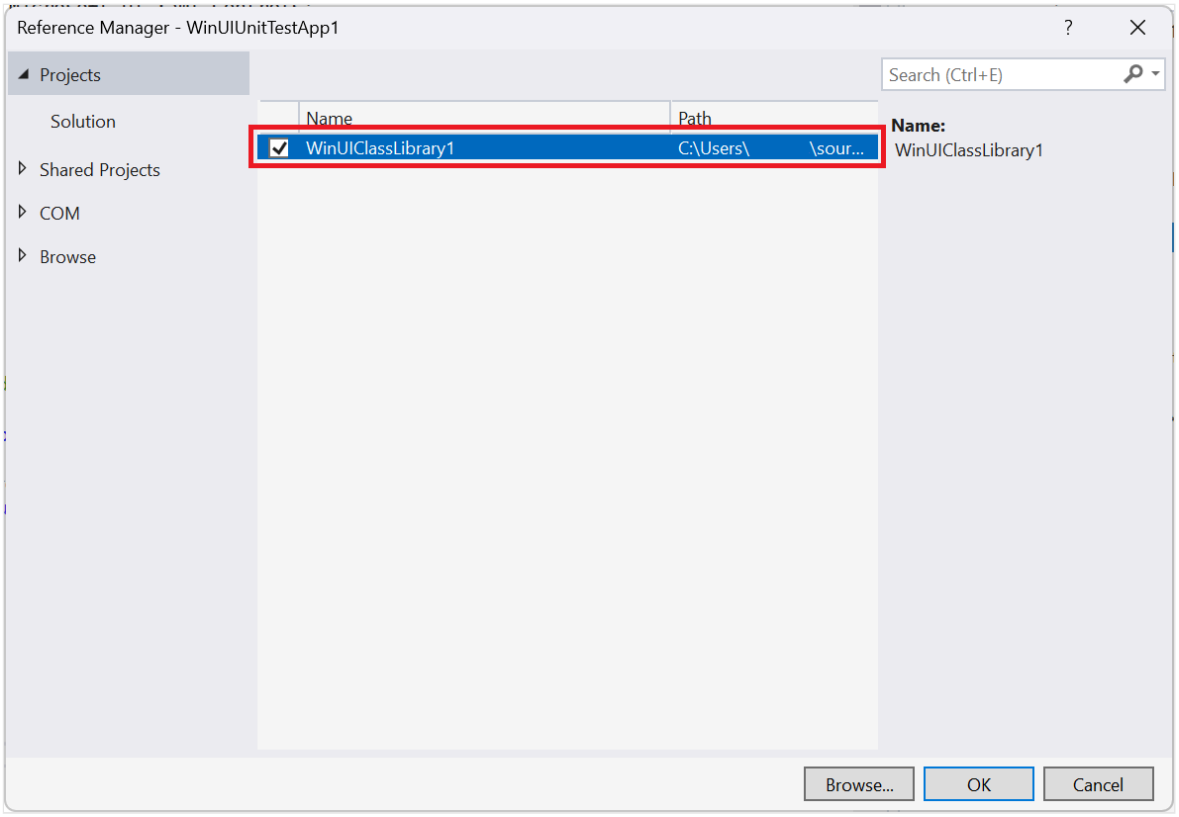
```
namespace WinUIClassLibrary1
{
  public sealed partial class UserControll : UserControl
  {
      public UserControl1()
      {
          this.InitializeComponent();
      }

      public int GetSeven()
      {
          return 7;
      }
  }
}
```

12. Set the WinUI Class Library project as a dependency of the unit test project to enable the use of types from the WinUI class library project. In Solution Explorer, under the class library project, right click on **Dependencies** and select **Add Project Reference**.



Select the "WinUIClassLibrary1" item from the **Projects** list.

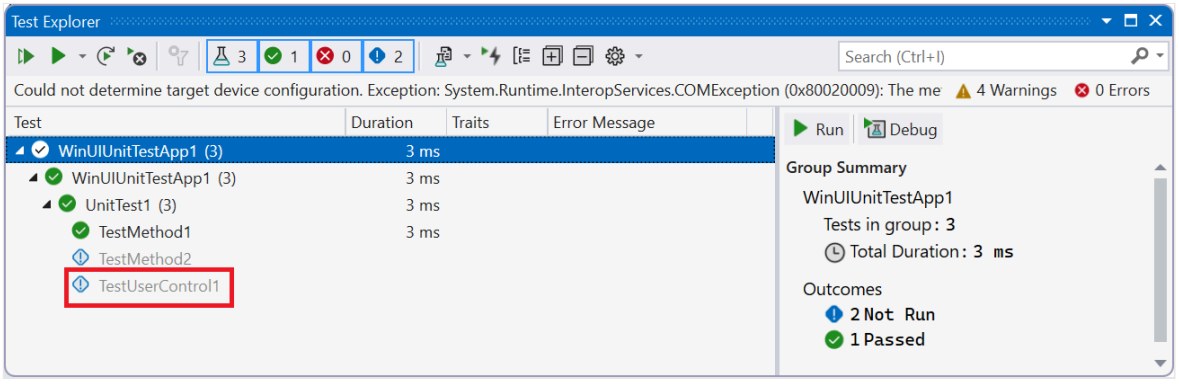


13. Create a new test method in UnitTests.cs. As this test case requires a XAML UI Thread to run, mark it with the [UITestMethod] attribute instead of the standard [TestMethod] attribute.

C#

```
[UITestMethod]
public void TestUserControl1()
{
   WinUIClassLibrary1.UserControl1 userControl1 = new
WinUIClassLibrary1.UserControl1();
   Assert.AreEqual(7, userControl1.GetSeven());
}
```

This new test method now appears in **Test Explorer** as one of your unit tests.



14. Run tests.

- Right click the new test node and select **Run**.
- Select the new test and either press the **Play** button or press **Ctrl + R, T**.
- Press the **Run All Tests In View** button or press **Ctrl + R, V**.

Build Windows apps with .NET MAUI

Article • 01/23/2025

.NET Multi-platform App UI (.NET MAUI) is a cross-platform framework for creating native mobile and desktop apps with C# and *optionally* XAML. Using .NET MAUI, you can develop apps that can run on Windows, Android, iOS, macOS, and Samsung Tizen from a single shared code-base. If you build a Windows app with .NET MAUI, it will use WinUI 3 as its native platform, and therefore run on Windows 10 version 1809 or later and Windows 11.

Why use .NET MAUI on Windows?

Building apps for Windows with .NET MAUI provides several benefits:

- **Native on Windows**: .NET MAUI creates a WinUI app when targeting Windows. This means that your .NET MAUI app will provide the same user experience on Windows as your Windows App SDK applications.
- **User interface in code**: The .NET MAUI Community Toolkit includes C# Markup, a set of fluent helper methods for building user interfaces in C# code. This enables a separation of concerns between the UI and the business logic of your app, just as with XAML. C# Markup is available on all platforms supported by .NET MAUI.
- **Cross-platform**: Take your Windows apps to all supported platforms, including Android, iOS, macOS, and Samsung Tizen devices.
- **Simplicity**: Develop in a single shared project that can target every platform supported by .NET MAUI.
- **Hot Reload**: Save time while debugging with .NET Hot Reload and XAML Hot Reload support in .NET MAUI. Make edits while the app is running and the changes are automatically applied.
- **Native APIs**: .NET MAUI provides cross-platform APIs for native features on each platform. For native APIs that are not available in .NET MAUI's cross-platform APIs, you can invoke platform-specific code.

If you are planning to build a new app for Windows and want to target additional platforms, you should consider using .NET MAUI. If you are only targeting Windows with your app, there are some good reasons to continue using the Windows App SDK:

- **Familiarity**: .NET MAUI XAML and Windows App SDK XAML have some differences. If you are comfortable with XAML in UWP and Windows App SDK, you will have a bit of a learning curve with the .NET MAUI controls and XAML syntax.

- **Native Controls**: .NET MAUI does not currently support using Windows App SDK controls. If you have existing controls from other Windows App SDK projects you intend to re-use or rely on 3rd Party or open source controls, you will need to find alternatives for .NET MAUI projects.
- **Closer to Windows**: When writing .NET MAUI apps, it outputs a Windows App SDK app, but there is some translation to get from your code to the native Windows app. With Windows App SDK, you are eliminating that translation step and are less likely to encounter issues with styles, API compatibility, or layout.

> **Tip**
>
> Are you still deciding between .NET MAUI, WinUI, and other UI framework options? Check out the **Windows developer FAQ** to learn about the different options for building native Windows apps. Then go watch the **Windows Dev Chat** episode on **Choosing your ideal dev platform**. The segment about **.NET MAUI** hosted by Beth Massi walks through examples and reasons for choosing .NET MAUI for your next app.

Code samples

Explore the .NET MAUI code samples in the samples browser or on GitHub at dotnet/maui-samples.

Samples that demonstrate specific tasks

Expand table

Sample Name/Link	Task
Animations	**Use animations** to bring your app to life.
Behaviors	**Add functionality without subclassing** using behaviors, instead attaching behavior classes to your controls.
Control Templates	**Define the visual structure** of `ContentView` derived custom controls, and `ContentPage` derived pages.
Data Binding	**Bind objects** to the actual UI elements, responsively updating one another when one changes.
Shell App	**Use a .NET Shell app** to reduce complexity, reuse code, and integrate existing Windows functionality (such as URI navigation and integrated search bars) into your app.
Triggers	**Use triggers** to selectively update, hide, or display specific controls when an event or data changes.

Get started with .NET MAUI on Windows

To get started with .NET MAUI on Windows, install Visual Studio 2022 version 17.3 or later.

- Download 2022 Community
- Download 2022 Professional
- Download 2022 Enterprise

When installing or modifying Visual Studio, select the **.NET Multi-platform App UI development** workload with the default optional installation options selected. For more information about managing workloads in Visual Studio, see Modify Visual Studio workloads, components, and language packs. If you are using Visual Studio Code and the .NET CLI, you will use the dotnet workload command for workload management.

If you haven't enabled development mode on your PC, see Enable your device for development. If it isn't enabled, Visual Studio will prompt you to enable development mode when you try to run your first .NET MAUI project on Windows.

.NET MAUI Community Toolkit documentation

Build your first .NET MAUI app for Windows

Article • 01/23/2025

Get hands-on with .NET MAUI by building your first cross-platform app on Windows.

Introduction

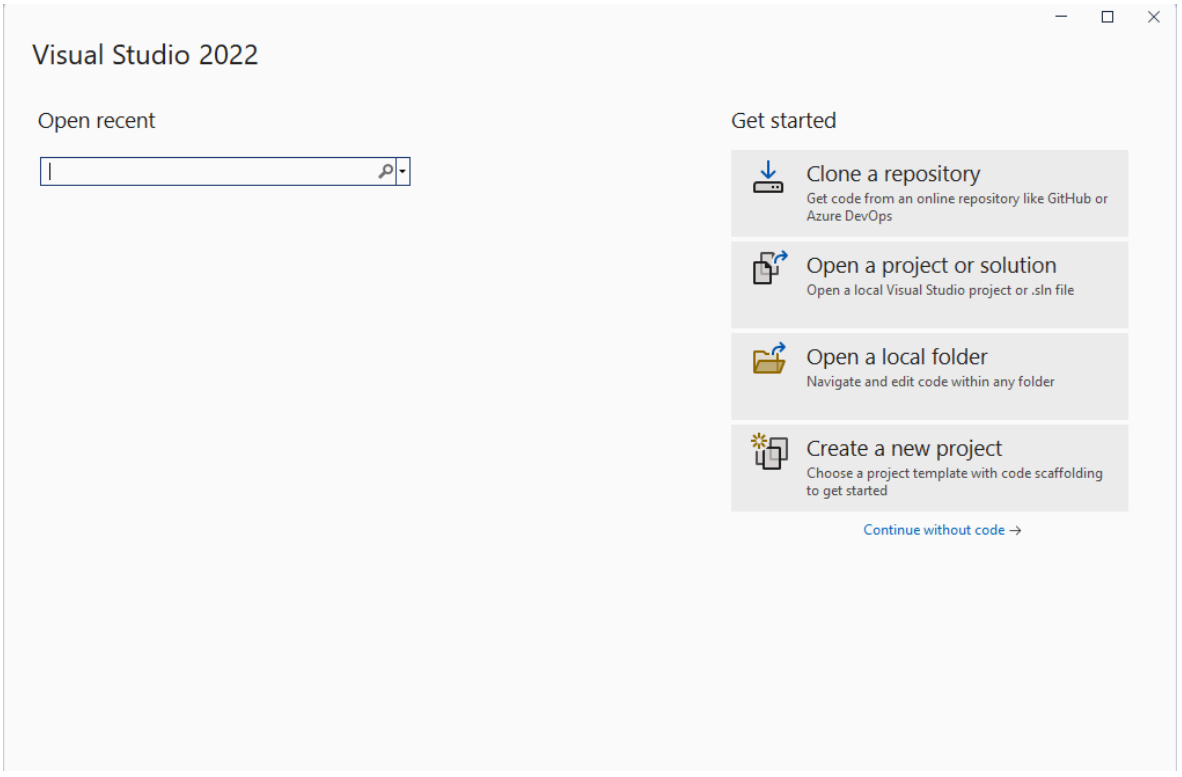
In this tutorial, you'll learn how to create and run your first .NET MAUI app for Windows in Visual Studio 2022 (17.3 or later). We will add some MVVM Toolkit features from the .NET Community Toolkit to improve the design the default project.

Setting up the environment

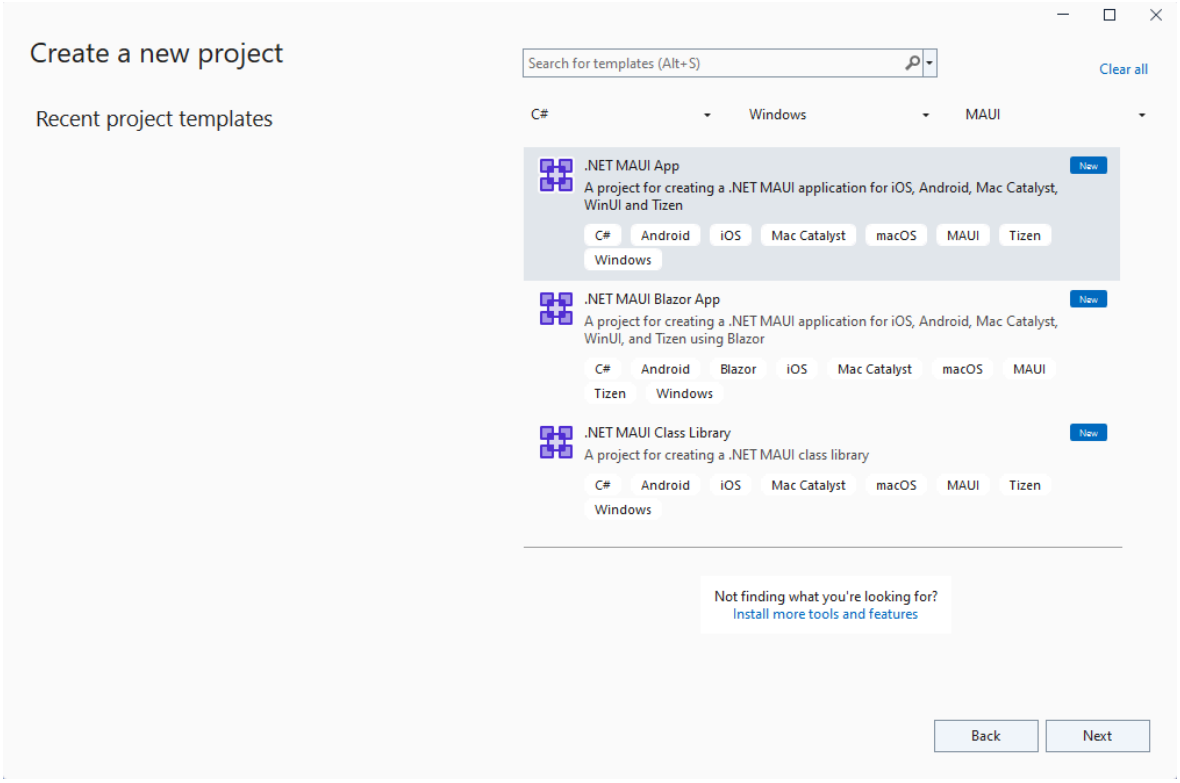
If you haven't already set up your environment for .NET MAUI development, please follow the steps to Get started with .NET MAUI on Windows.

Creating the .NET MAUI project

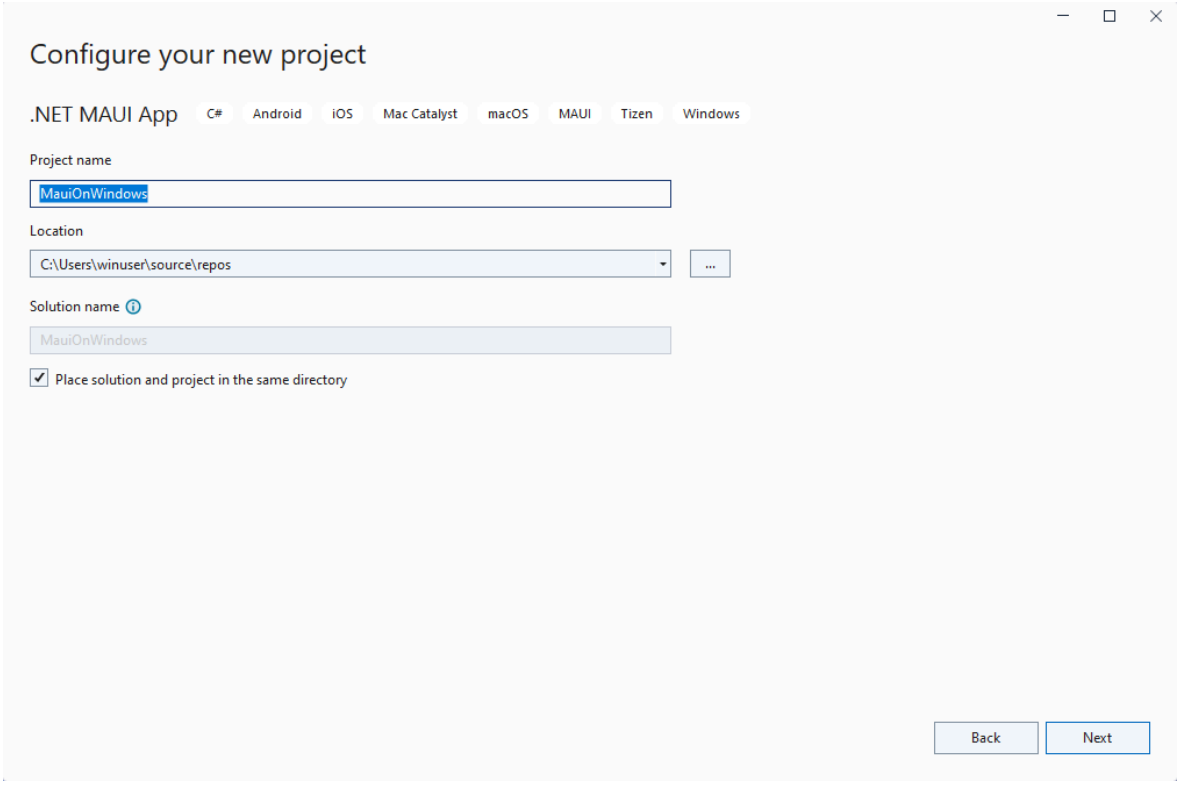
1. Launch Visual Studio, and in the start window click **Create a new project** to create a new project:



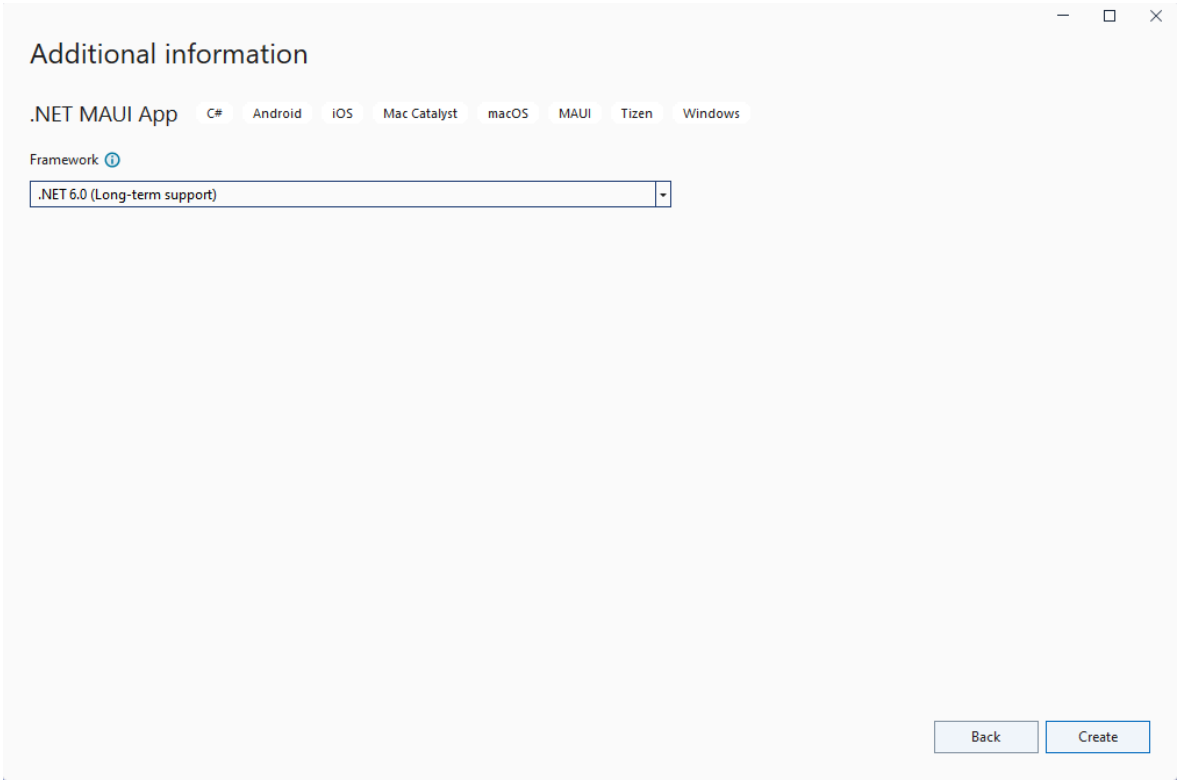
2. In the **Create a new project** window, select **MAUI** in the All project types drop-down, select the **.NET MAUI App** template, and click the **Next** button:



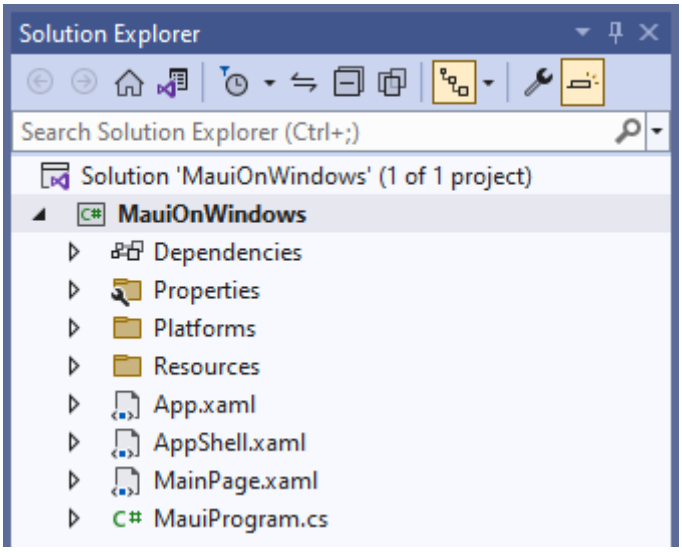
3. In the **Configure your new project** window, give your project a name, choose a location for it, and click the **Next** button:



4. In the **Additional information** window, click the **Create** button:

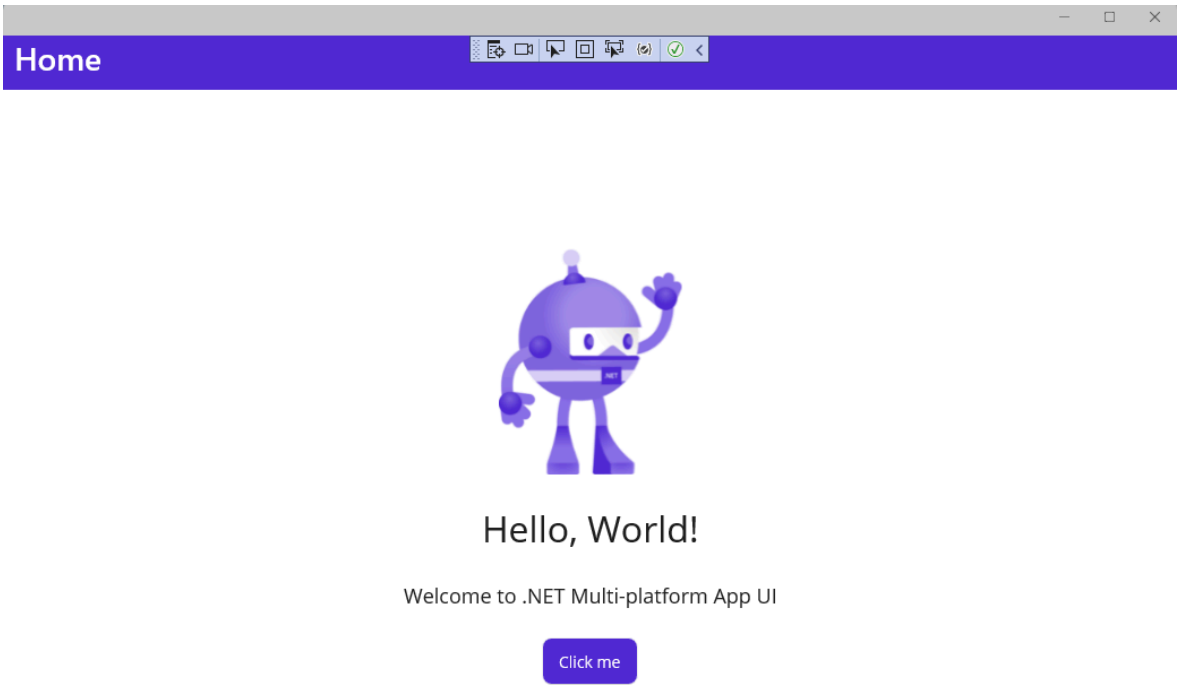


5. Wait for the project to be created, and for its dependencies to be restored:



6. In the Visual Studio toolbar, press the Windows Machine button to build and run the app.

7. In the running app, press the **Click me** button several times and observe that the count of the number of button clicks is incremented:



You just ran your first .NET MAUI app on Windows. In the next section, you'll learn how to add data binding and messaging features from the **MVVM Toolkit** to your app.

Troubleshooting

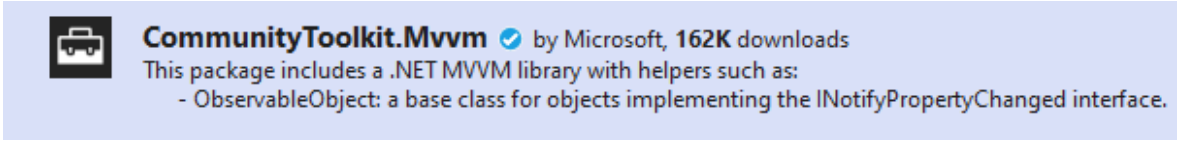
If your app fails to compile, review Troubleshooting known issues, which may have a solution to your problem.

Adding the MVVM Toolkit

Now that you have your first .NET MAUI app running on Windows, let's add some MVVM Toolkit features to the project to improve the app's design.

1. Right-click the project in **Solution Explorer** and select **Manage NuGet Packages...** from the context menu.

2. In the **NuGet Package Manager** window, select the **Browse** tab and search for **CommunityToolkit.MVVM**:

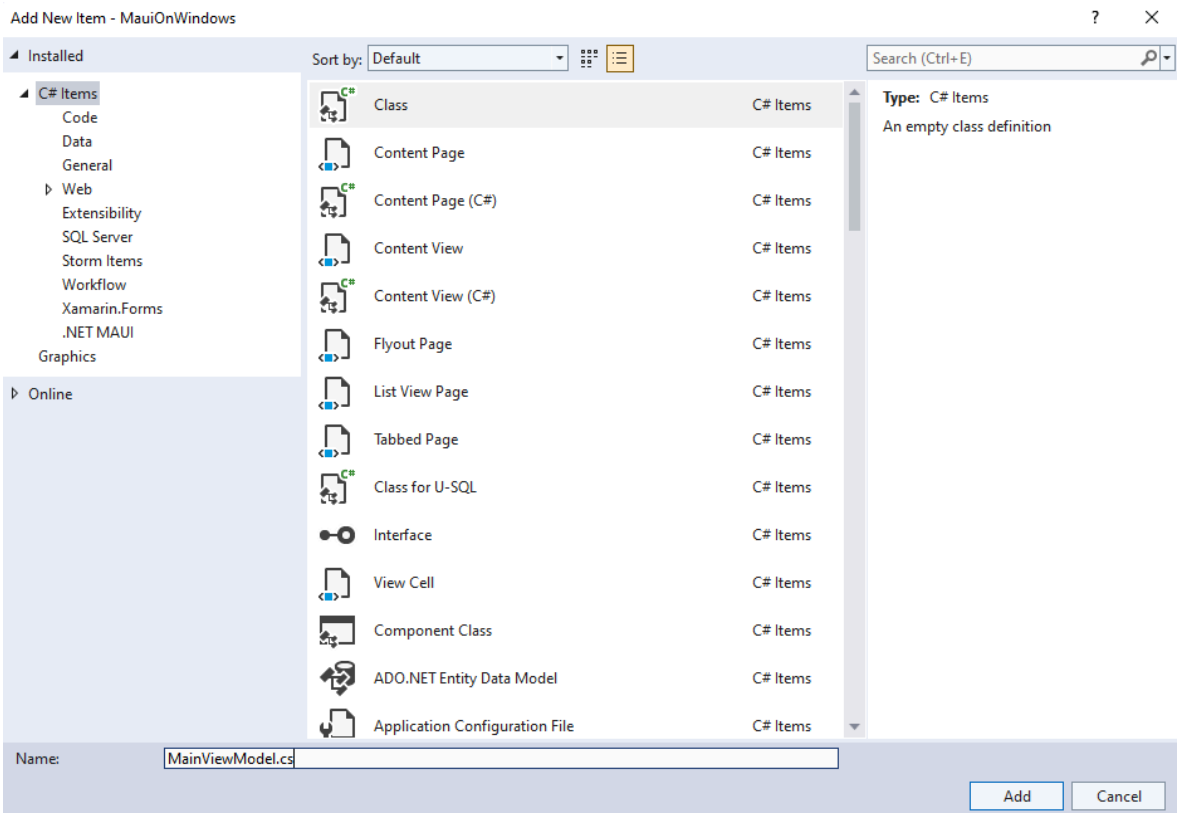


3. Add the latest stable version of the **CommunityToolkit.MVVM** package (version 8.0.0 or later) to the project by clicking **Install**.

4. Close the **NuGet Package Manager** window after the new package has finished installing.

5. Right-click the project again and select **Add | Class** from the context menu.

6. In the **Add New Item** window that appears, name the class `MainViewModel` and click **Add**:



7. The `MainViewModel` class will be the data binding target for the `MainPage`. Update it to inherit from `ObservableObject` in the `CommunityToolkit.Mvvm.ComponentModel` namespace This will also require updating the class to be `public` and `partial`.

8. The `MainViewModel` class will contain the following code. The `CountChangedMessage` record defines a message that is sent each time the Click me button is clicked, notifying the view of the change. The ObservableProperty and RelayCommand attributes added to the `message` and `IncrementCounter` members are source generators provided by the MVVM Toolkit to create the MVVM boilerplate code for `INotifyPropertyChanged` and `IRelayCommand` implementations. The `IncrementCounter` method's implementation contains the logic from `OnCounterClicked` in MainPage.xaml.cs, with a change to send a message with the new counter message. We will be removing that code-behind code later.

C#

```
using CommunityToolkit.Mvvm.ComponentModel;
using CommunityToolkit.Mvvm.Input;
using CommunityToolkit.Mvvm.Messaging;

namespace MauiOnWindows
{
    public sealed record CountChangedMessage(string Text);

    public partial class MainViewModel : ObservableObject
    {
        [ObservableProperty]
        private string message = "Click me";

        private int count;

        [RelayCommand]
        private void IncrementCounter()
        {
            count++;

            // Pluralize the message if the count is greater than 1
            message = count == 1 ? $"Clicked {count} time" : $"Clicked
{count} times";

            WeakReferenceMessenger.Default.Send(new
CountChangedMessage(message));
        }
    }
}
```

> **Note**
>
> You will need to update the namespace in the previous code to match the namespace in your project.

9. Open the **MainPage.xaml.cs** file for editing and remove the `OnCounterClicked` method and the `count` field.

10. Add the following code to the `MainPage` constructor after the call to `InitializeComponent()`. This code will receive the message sent by `IncrementCounter()` in the `MainViewModel` and will update the `CounterBtn.Text` property with the new message and announce the new text with the `SemanticScreenReader`:

C#

```
WeakReferenceMessenger.Default.Register<CountChangedMessage>(this, (r,
m) =>
{
    CounterBtn.Text = m.Text;
    SemanticScreenReader.Announce(m.Text);
});
```

11. You will also need to add a `using` statement to the class:

```
C#

using CommunityToolkit.Mvvm.Messaging;
```

12. In `MainPage.xaml`, add a namespace declaration to the `ContentPage` so the `MainViewModel` class can be found:

```
XAML

xmlns:local="clr-namespace:MauiOnWindows"
```

13. Add `MainViewModel` as the `BindingContext` for the `ContentPage`:

```
XAML

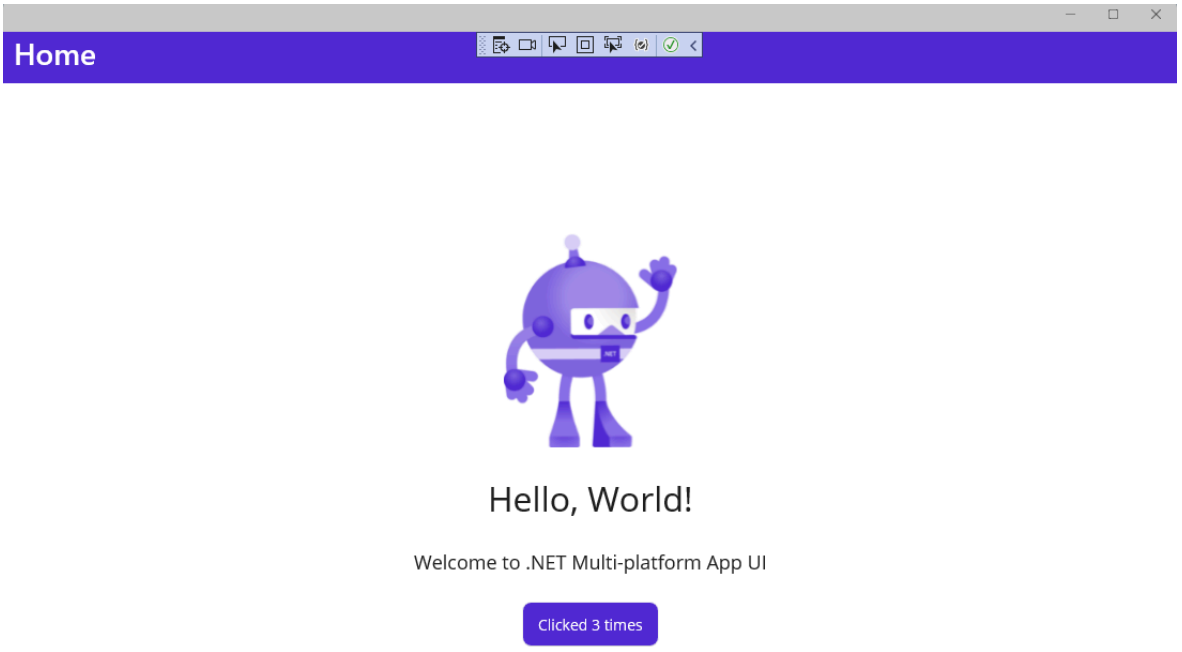
<ContentPage.BindingContext>
    <local:MainViewModel/>
</ContentPage.BindingContext>
```

14. Update the `Button` on `MainPage` to use a `Command` instead of handling the `Clicked` event. The command will bind to the `IncrementCounterCommand` public property that is generated by the MVVM Toolkit's source generators:

```
XAML

<Button
    x:Name="CounterBtn"
    Text="Click me"
    SemanticProperties.Hint="Counts the number of times you click"
    Command="{Binding Path=IncrementCounterCommand}"
    HorizontalOptions="Center" />
```

15. Run the project again and observe that the counter is still incremented when you click the button:



16. While the project is running, try updating the "Hello, World!" message in the first Label to read "Hello, Windows!" in **MainPage.xaml**. Save the file and notice that XAML Hot Reload updates the UI while the app is still running:

Using the Microsoft Graph API with .NET MAUI on Windows

Tutorial: Create a .NET MAUI app using the Microsoft Graph SDK

Article • 07/13/2023

Get hands-on with .NET MAUI by building a cross-platform app on Windows that leverages the Microsoft Graph SDK to display user data.

In this tutorial, you learn how to:

- ✓ Set up your environment for .NET MAUI development and create a .NET MAUI project
- ✓ Register your client app in Azure
- ✓ Integrate with Azure Identity and the Microsoft Graph SDK
- ✓ Update the user interface to display user information from Microsoft Graph

Prerequisites

- An Azure account with an active subscription. Create an account for free.
- The .NET MAUI installation requirements.
- If you are new to .NET MAUI on Windows, you should start with the Build your first .NET MAUI app for Windows tutorial.

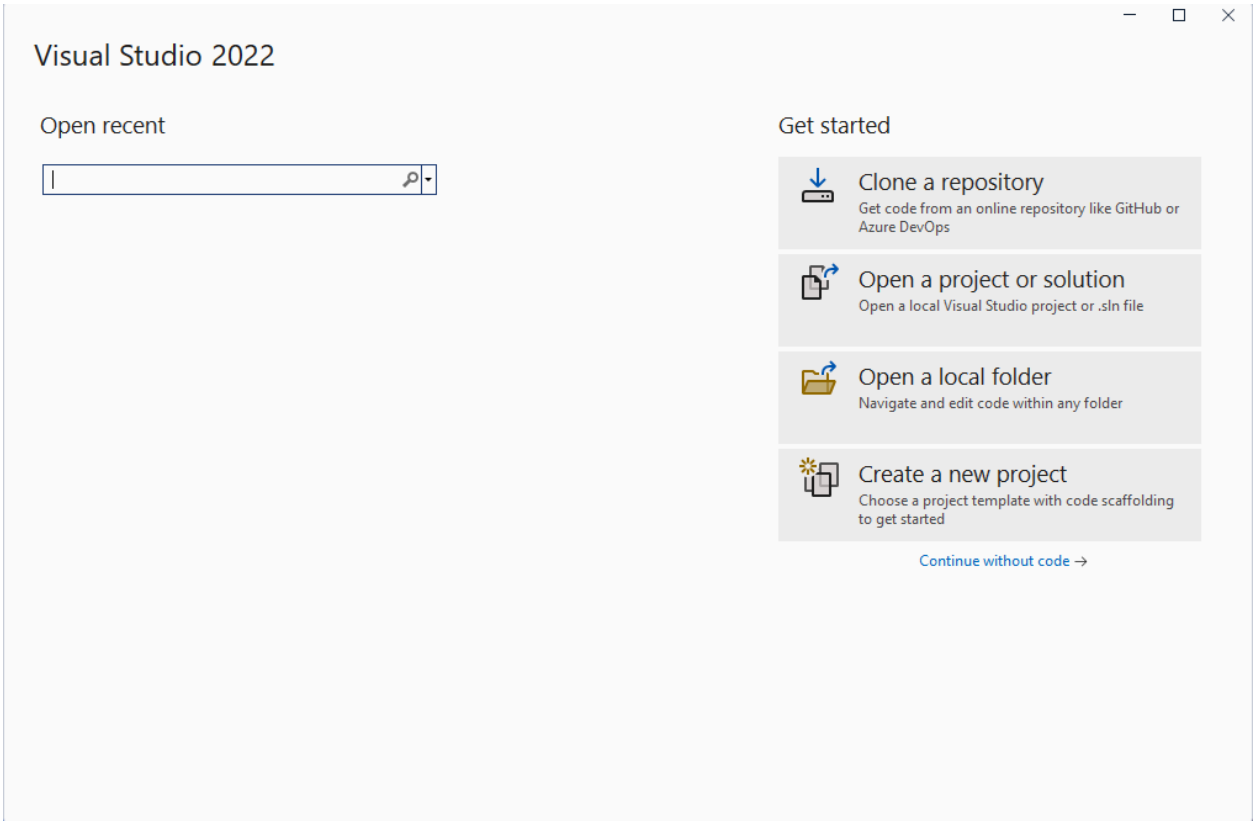
Setting up the environment

If you haven't already set up your environment for .NET MAUI development, please follow the steps to Get started with .NET MAUI on Windows.

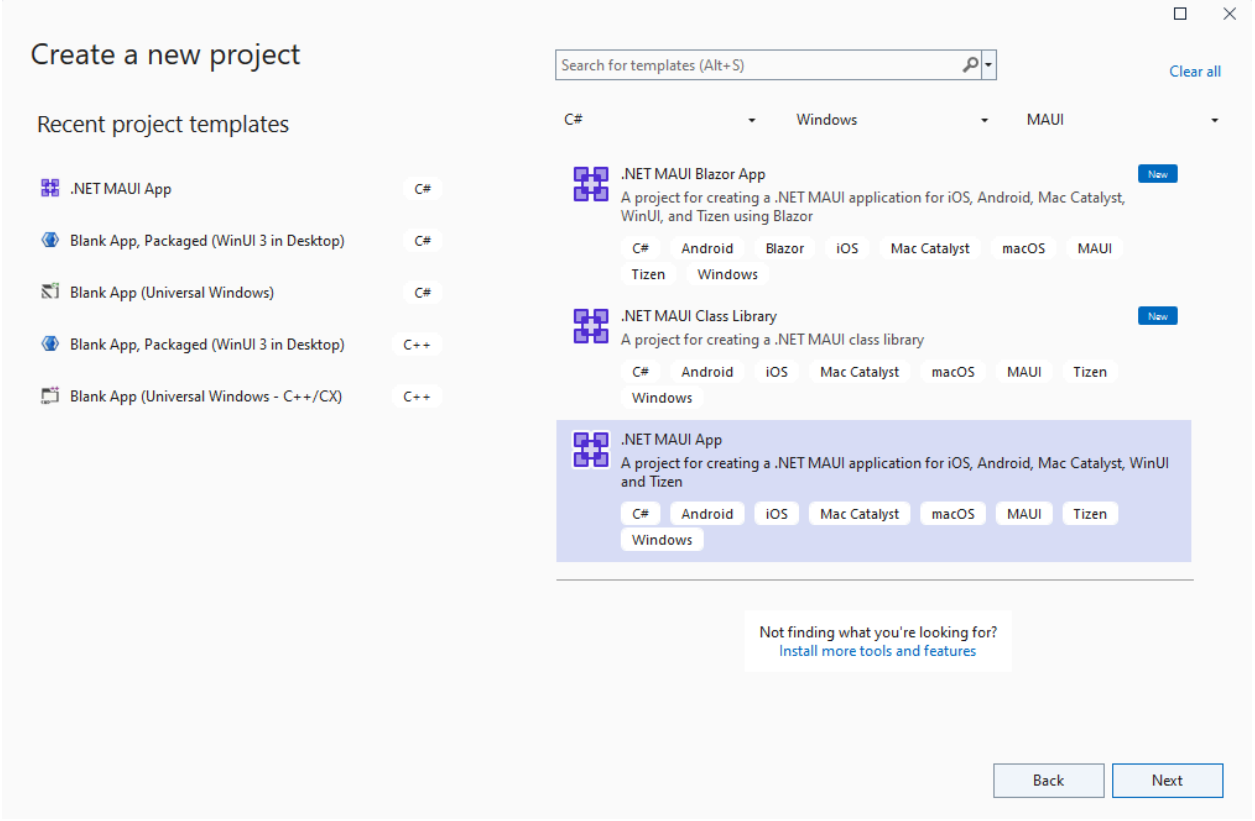
Creating the .NET MAUI project

> ⓘ **Note**
>
> If you are already familiar with setting up a .NET MAUI project, you can skip to the Register your client in Azure section.

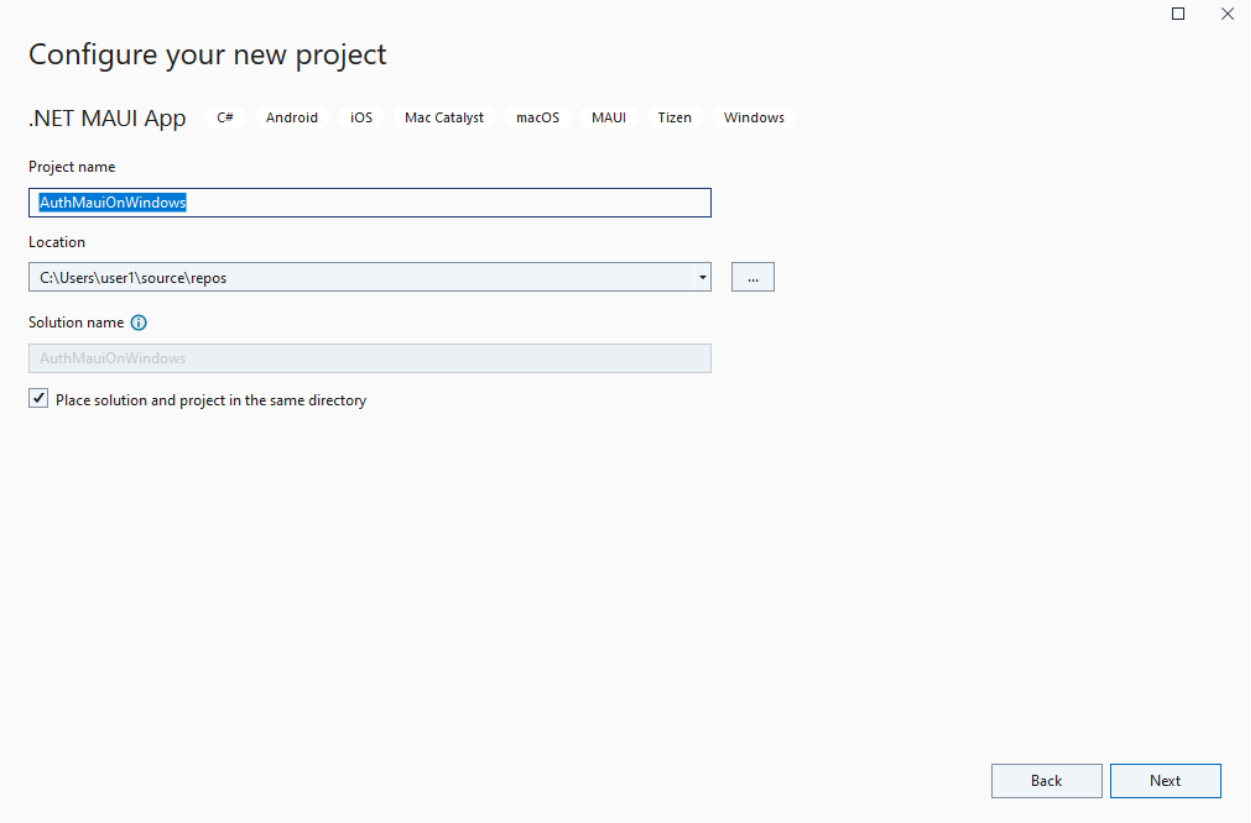
Launch Visual Studio, and in the start window click **Create a new project** to create a new project:



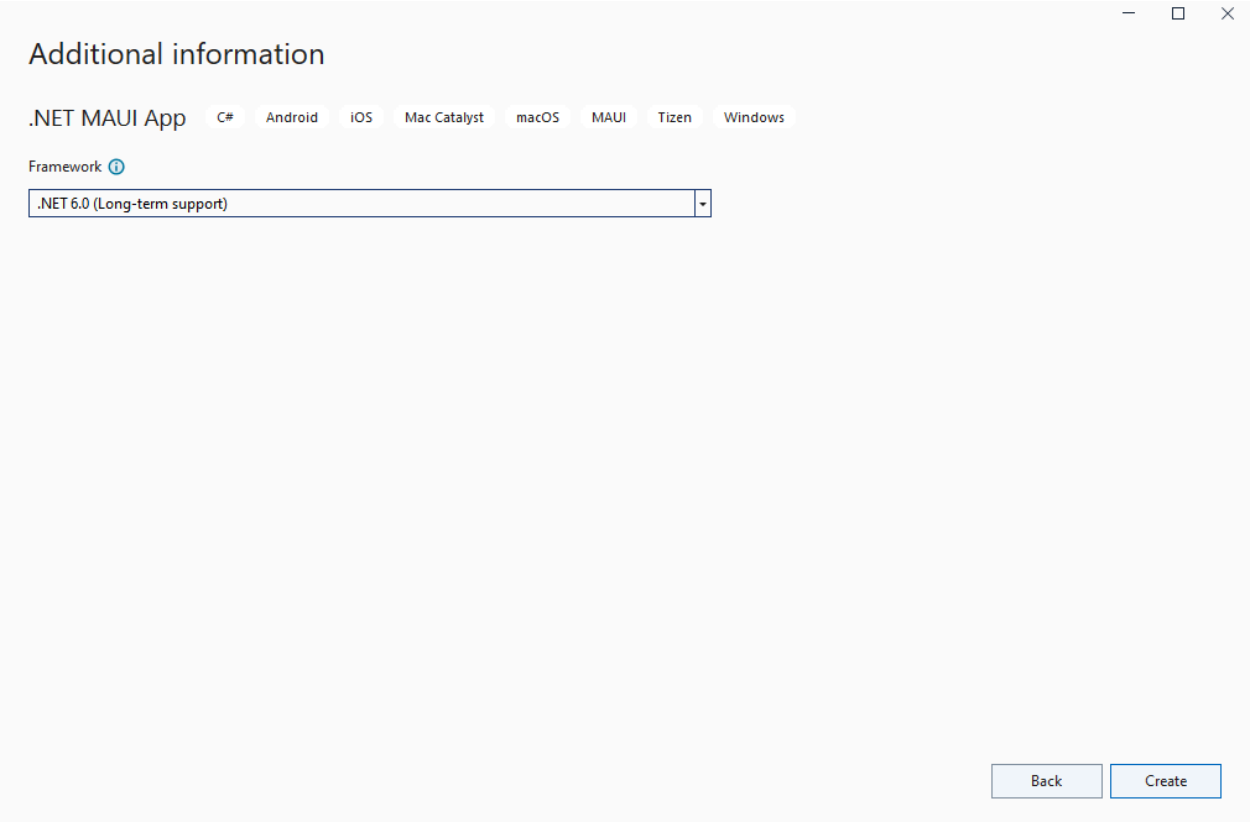
In the **Create a new project** window, select **MAUI** in the All project types drop-down, select the **.NET MAUI App** template, and click the **Next** button:



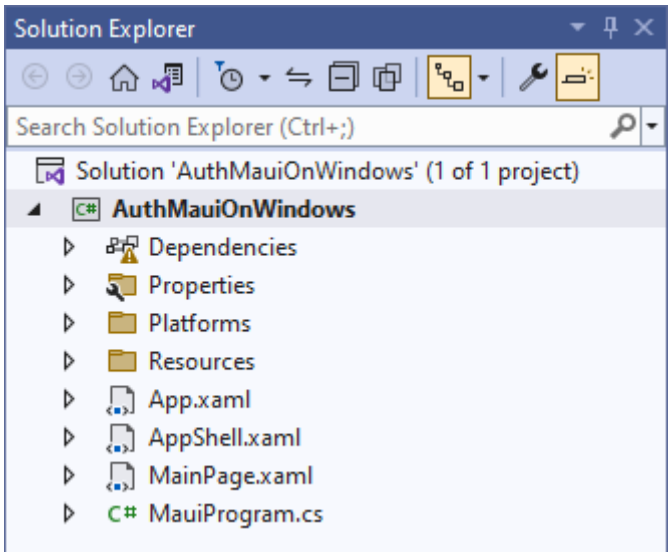
In the **Configure your new project** window, give your project a name, choose a location for it, and click the **Next** button:



In the **Additional information** window, click the **Create** button:



Wait for the project to be created, and for its dependencies to be restored:



In the Visual Studio toolbar, press the **Windows Machine** button to build and run the app. Click the **Click me** button and verify that the button content updates with the number of clicks.

Now that you have verified that the .NET MAUI app on Windows is working as expected, we can integrate the Graph SDK. In the next section, you'll add the packages necessary to authenticate and make calls to Microsoft Graph.

Register your client in Azure

An **app registration** in Azure with the **User.Read** scope granted to the app is required to read user data from Microsoft Graph. To register your application, follow these steps:

Sign in to the Azure portal.

If you have access to multiple tenants, use the **Directories + subscriptions** filter in the top menu to switch to the tenant in which you want to register the application.

Search for and select **Azure Active Directory**.

Under **Manage**, select **App registrations** > **New registration**.

Enter a **Name** for your application, for example `Win-App-calling-MsGraph`. Users of your app might see this name, and you can change it later.

In the Supported account types section, select Accounts in any organizational directory and personal Microsoft accounts (for example, Skype, Xbox, Outlook.com).

Select Register to create the application.

Copy and save the of the **Application (client) ID** and the **Directory (tenant) ID** values for later use. We will store those values in the GraphService class in the next section.

Under **Manage**, select **Authentication**.

Select **Add a platform** > **Mobile and desktop applications**.

In the **Redirect URIs** section, select `https://login.microsoftonline.com/common/oauth2/nativeclient` and in **Custom redirect URIs** add `http://localhost`.

Select **Configure**.

Under **Manage**, select **API permissions**.

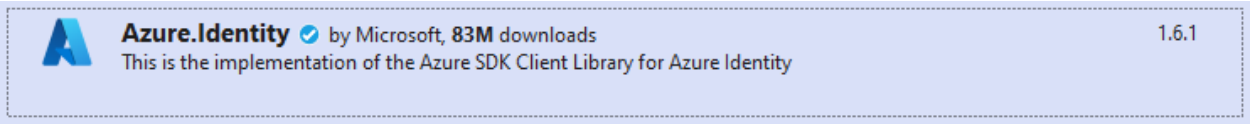
If the Microsoft Graph **User.Read** permission is not present under **Configured permissions**, select **Add permission**. In the **Request API permissions** screen, select **Microsoft Graph** > **Application permissions** and search for **User.Read**. Expand **User**, select **User.Read**, and click **Add permissions**.

Integrate the Graph SDK and Azure Identity

Now that you have your .NET MAUI app running on Windows and have configured the app registration in Azure, let's add a couple of NuGet packages to the project to integrate with Azure Identity and Microsoft Graph.

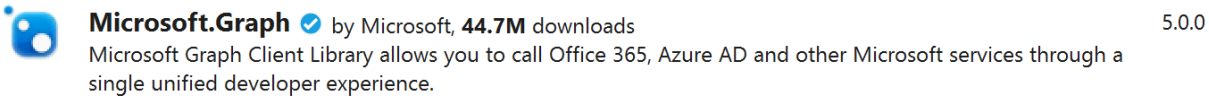
Right-click the project in **Solution Explorer** and select **Manage NuGet Packages...** from the context menu.

In the **NuGet Package Manager** window, select the **Browse** tab and search for **Azure.Identity**:



Add the latest stable version of the **Azure.Identity** package to the project by clicking **Install**.

Next, search for **Microsoft.Graph**:

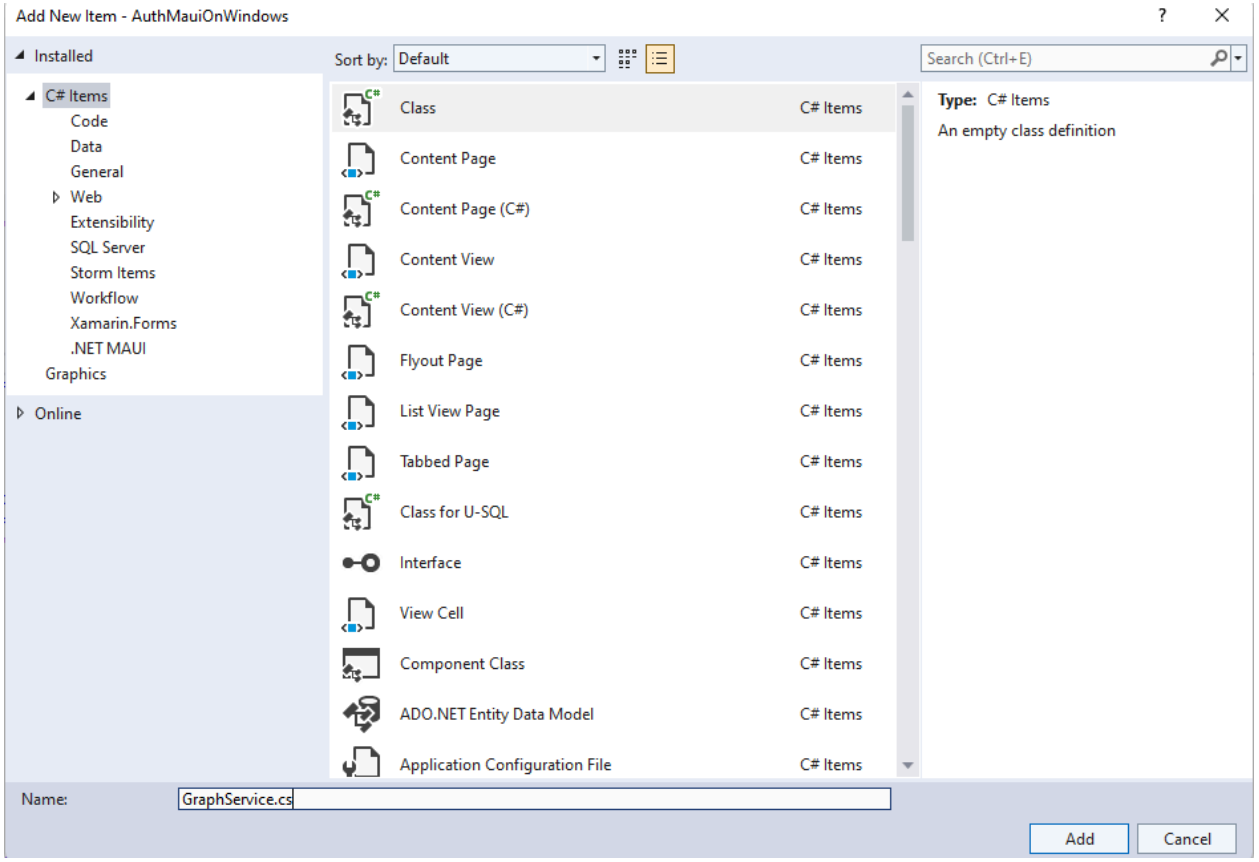


Add the latest stable version of the **Microsoft.Graph** package to the project by clicking **Install**.

Close the **NuGet Package Manager** window after the new package has finished installing.

Right-click the project again and select **Add | Class** from the context menu.

In the **Add New Item** window that appears, name the class `GraphService` and click **Add**:



Add four private members to the `GraphService` class, substituting your own *client ID* and *tenant ID* values for the placeholder text:

C#

```
private readonly string[] _scopes = new[] { "User.Read" };
private const string TenantId = "<add your tenant id here>";
private const string ClientId = "<add your client id here>";
private GraphServiceClient _client;
```

Add an `Initialize()` method to `GraphService`, which will be called from the constructor. The initialization code will authenticate using the `InteractiveBrowserCredential` class. Upon successful authentication, the auth token will be provided to the `GraphServiceClient` by the credential class along with the requested scopes (`User.Read`).

C#

```
public GraphService()
{
    Initialize();
}

private void Initialize()
{
    // assume Windows for this sample
    if (OperatingSystem.IsWindows())
    {
        var options = new InteractiveBrowserCredentialOptions
        {
            TenantId = TenantId,
            ClientId = ClientId,
            AuthorityHost = AzureAuthorityHosts.AzurePublicCloud,
            RedirectUri = new Uri("http://localhost"),
        };

        InteractiveBrowserCredential interactiveCredential = new(options);
        _client = new GraphServiceClient(interactiveCredential, _scopes);
    }
    else
    {
        // TODO: Add iOS/Android support
    }
}
```

> **Note**
>
> The 'Initialize()' method currently only supports Windows. Authenticating on iOS and Android requires a different NuGet package (Microsoft.Identity.Client) and some additional steps. To read more about mobile authentication, see Configure a native client application.

Add a public async method named `GetMyDetailsAsync()` to return the `User` object for the authenticated user:

C#

```
public async Task<User> GetMyDetailsAsync()
{
    try
    {
        return await _client.Me.GetAsync();
    }
    catch (Exception ex)
    {
        Console.WriteLine($"Error loading user details: {ex}");
        return null;
```

```
    }
}
```

Two `using` statements will be needed to compile the new code added to `GraphService`:

C#

```
using Azure.Identity;
using Microsoft.Graph;
using Microsoft.Graph.Models;
```

In **MainPage.xaml**, add an `x:Name` to the **Hello, World!** label:

XAML

```
<Label
    x:Name="HelloLabel"
    Text="Hello, World!"
    SemanticProperties.HeadingLevel="Level1"
    FontSize="32"
    HorizontalOptions="Center" />
```

Add a new button to the page after the existing `CounterBtn` to get the user information from Graph:

XAML

```
<Button
    x:Name="GetUserInfoBtn"
    Text="Load User Info"
    SemanticProperties.Hint="Loads user information from Microsoft Graph"
    Clicked="GetUserInfoBtn_Clicked"
    HorizontalOptions="Center" />
```

In **MainPage.xaml.cs**, add private variables to for `GraphService` and `User`:

C#

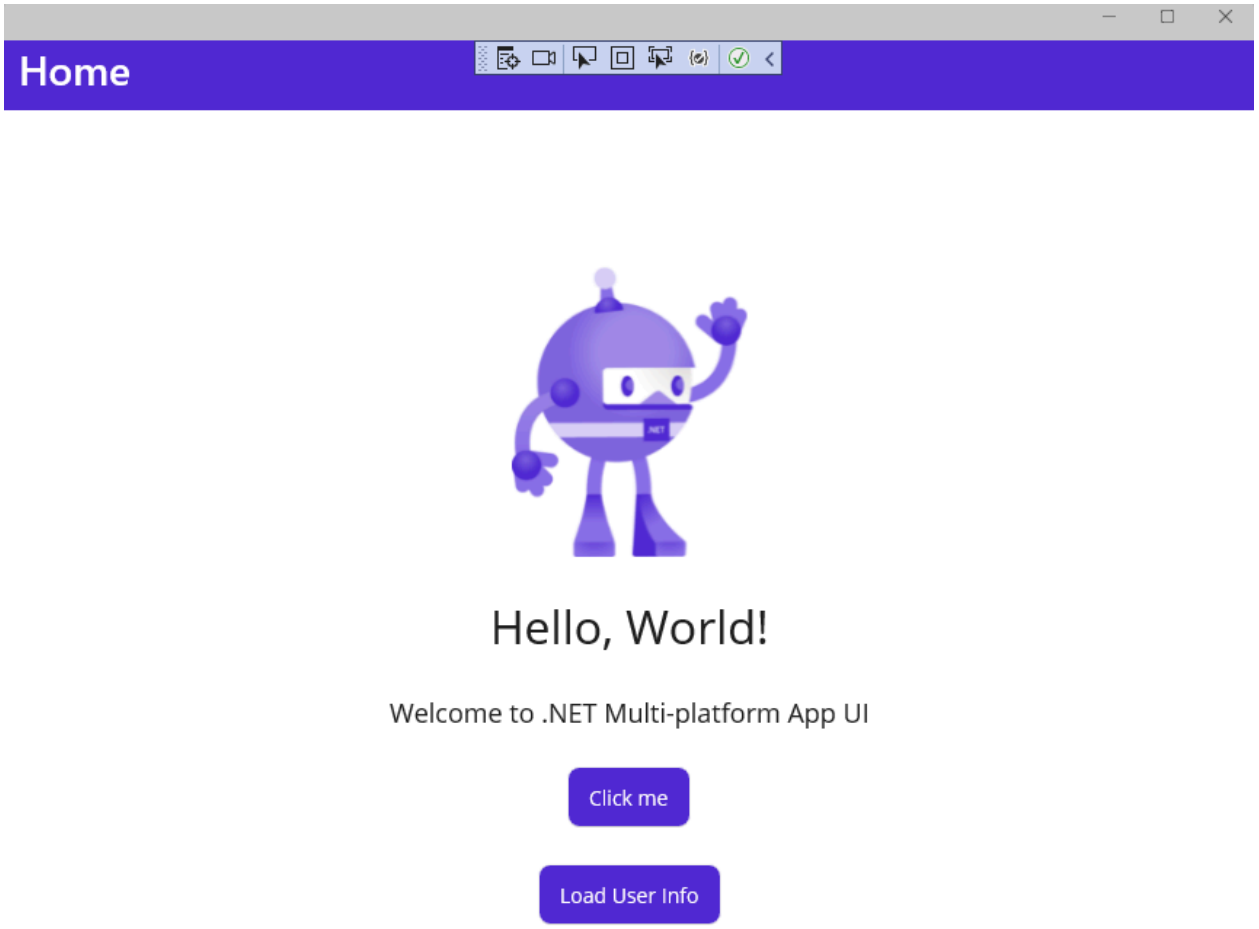
```
private GraphService graphService;
private User user;
```

Add an event handler for the `Clicked` event that you added to the `GetUserInfoButton` on **MainPage.xaml**. The event handler will create an instance of `GraphService` if it is null and make the call to fetch the user data. The `HelloLabel`'s text will be updated to say hello to the user, displaying the `DisplayName` property from Microsoft Graph:

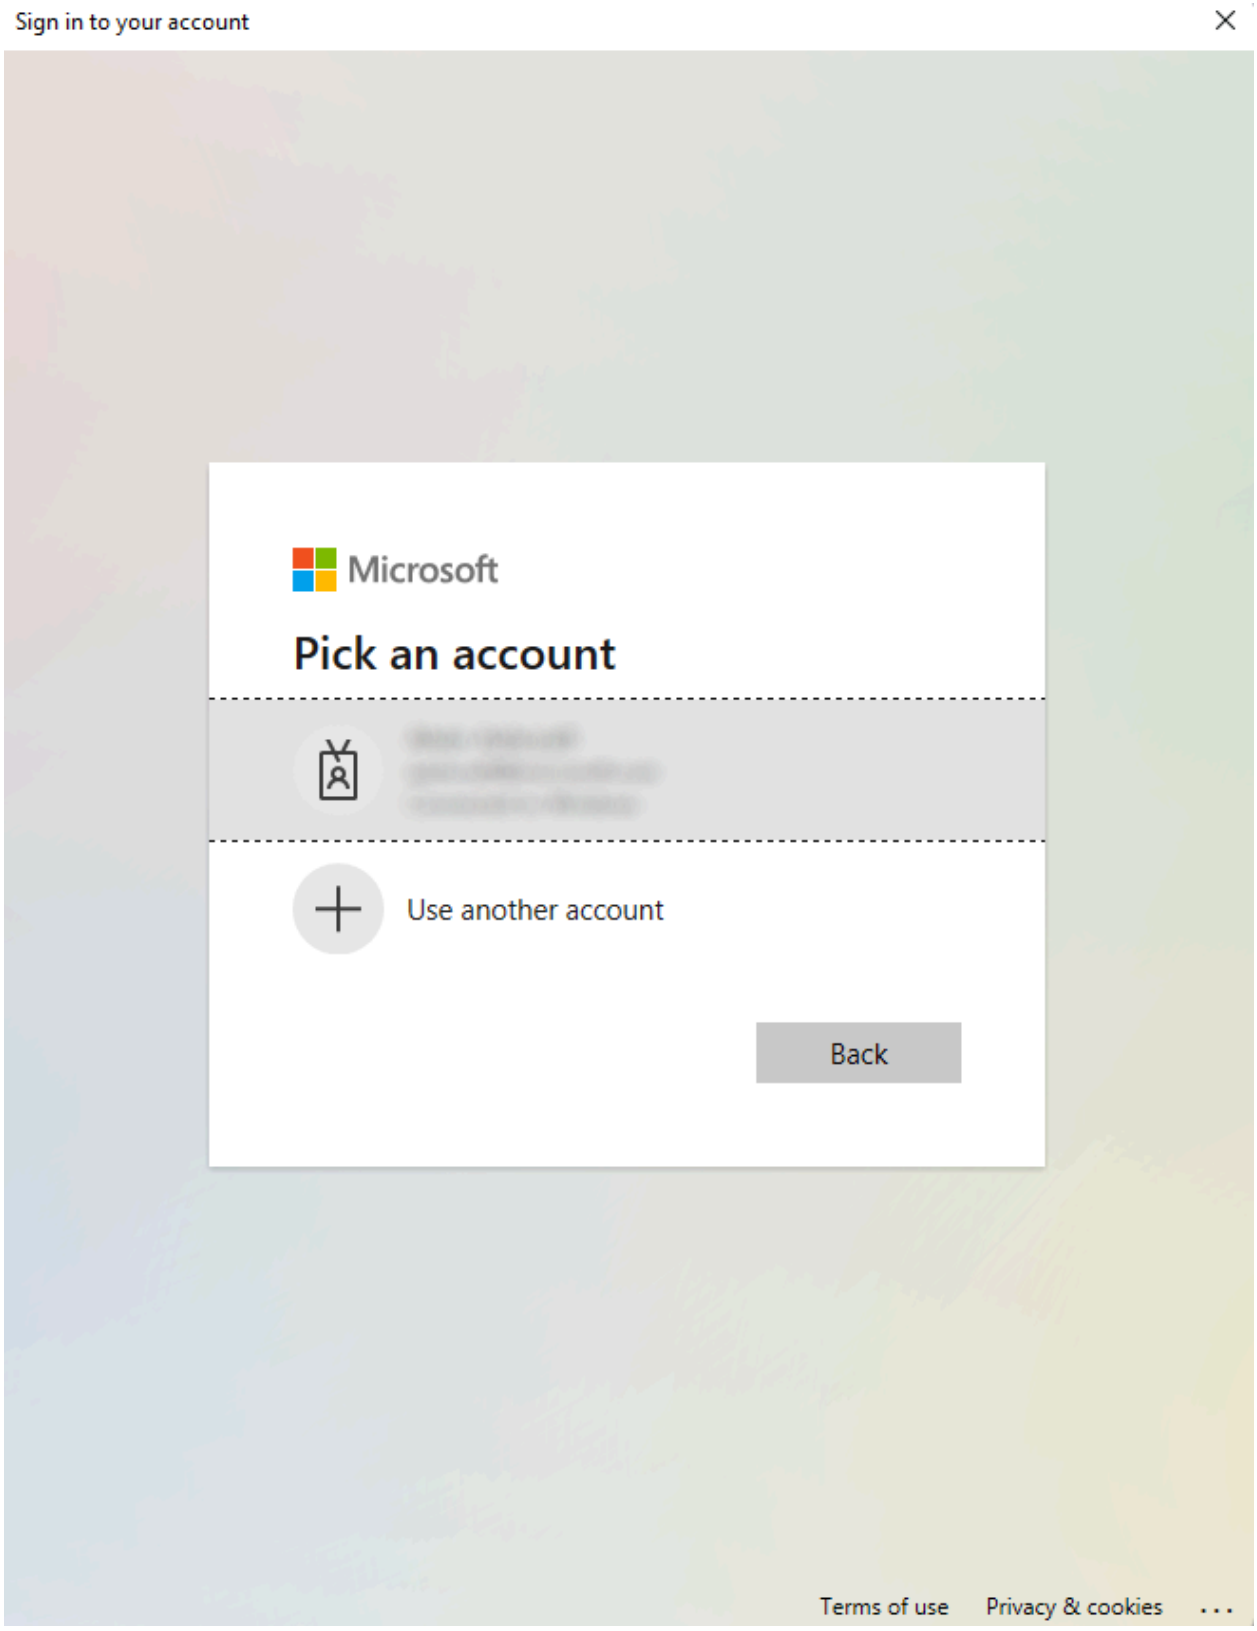
C#

```
private async void GetUserInfoBtn_Clicked(object sender, EventArgs e)
{
    if (graphService == null)
    {
        graphService = new GraphService();
    }
    user = await graphService.GetMyDetailsAsync();
    HelloLabel.Text = $"Hello, {user.DisplayName}!";
}
```

Run the app and click the **Load User Info** button:

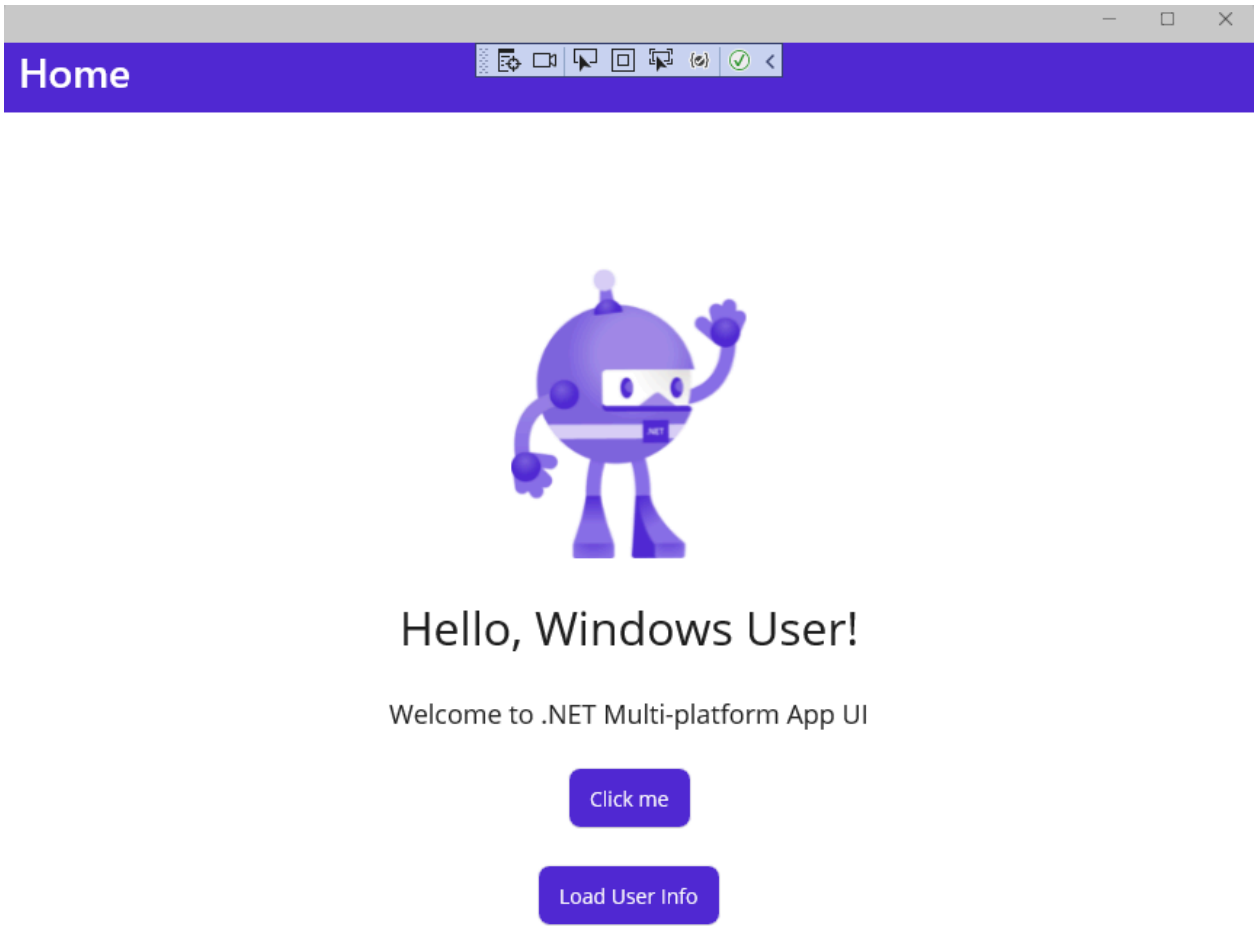


When the **Sign in to your account** window appears, select an existing account or click **Use another account**:



If you selected a different account, enter the email address and password for the account and sign in.

After the authentication completes, you will see your user's **DisplayName** in on the app:



Update the user interface to display user information

Now that the `GraphService` is returning user information, let's update the user interface to display some additional user profile information.

In MainPage.xaml, start by updating the contents of the `VerticalStackLayout`, removing the existing welcome label and `Image` control and adding four new labels to display the user information. Each label that will be updated is named, and we've provided some placeholder text until the data is loaded from the Graph query. The contents of the `VerticalStackLayout` should now look like this:

XAML

```
<VerticalStackLayout
    Spacing="25"
    Padding="30,0"
    VerticalOptions="Center">

    <Label
```

```
        x:Name="HelloLabel"
        Text="Hello, World!"
        SemanticProperties.Description="Displays a welcome message for the
user"
        SemanticProperties.HeadingLevel="Level1"
        FontSize="32"
        HorizontalOptions="Center" />

    <Button
        x:Name="CounterBtn"
        Text="Click me"
        SemanticProperties.Hint="Counts the number of times you click"
        Clicked="CounterBtn_Clicked"
        HorizontalOptions="Center" />

    <Button
        Text="Load User Info"
        SemanticProperties.Hint="Loads user information from Microsoft
Graph"
        Clicked="GetUserInfoBtn_Clicked"
        HorizontalOptions="Center" />

    <Label
        x:Name="DisplayNameLabel"
        Text="Display name"
        SemanticProperties.Description="Displays the user's display name
from Microsoft Graph."
        SemanticProperties.HeadingLevel="Level2"
        FontSize="18"
        HorizontalOptions="Center" />

    <Label
        x:Name="UserFirstNameLabel"
        Text="First name"
        SemanticProperties.Description="Displays the user's first name info
from Microsoft Graph"
        SemanticProperties.HeadingLevel="Level2"
        FontSize="18"
        HorizontalOptions="Center" />

    <Label
        x:Name="UserLastNameLabel"
        Text="Last name"
        SemanticProperties.Description="Displays the user's last name from
Microsoft Graph"
        SemanticProperties.HeadingLevel="Level2"
        FontSize="18"
        HorizontalOptions="Center" />

    <Label
        x:Name="UserPrincipalNameLabel"
        Text="User Principal Name"
        SemanticProperties.Description="Displays the user principal name
from Microsoft Graph"
        SemanticProperties.HeadingLevel="Level2"
```

```
        FontSize="18"
        HorizontalOptions="Center" />

</VerticalStackLayout>
```

Finally, in MainPage.xaml.cs, update the UI elements with the values of the new properties in the `GetUserInfoBtn_Clicked` event handler using the properties of the Graph User object:

C#

```
private async void GetUserInfoBtn_Clicked(object sender, EventArgs e)
{
    if (graphService == null)
    {
        graphService = new GraphService();
    }
    user = await graphService.GetMyDetailsAsync();
    HelloLabel.Text = $"Hello, {user.DisplayName}!";

    DisplayNameLabel.Text = user.DisplayName;
    UserFirstNameLabel.Text = user.GivenName;
    UserLastNameLabel.Text = user.Surname;
    UserPrincipalNameLabel.Text = user.UserPrincipalName;
}
```

Run the app again and click the **Load User Info** button. You should see your user information displayed in the app after authenticating:

Tutorial: Create a recommendation app with .NET MAUI and ChatGPT

Article • 06/17/2024

In this tutorial, you'll learn how to create a .NET MAUI app for Windows in Visual Studio that calls OpenAI's ChatGPT APIs to provide recommendations based on a location entered by the user. The app will have a simple UI that allows the user to enter a location and get recommendations for restaurants, hotels, and attractions.

In this tutorial, you learn how to:

- ✓ Create a simple user interface for your .NET MAUI app
- ✓ Reference and bootstrap the **OpenAI .NET API** library
- ✓ Use an API key to link your app to an OpenAI API account
- ✓ Make calls to the OpenAI chat APIs to get recommendations

Prerequisites

- An OpenAI account
- An OpenAI API key
- The .NET MAUI installation requirements
- If you are new to .NET MAUI on Windows, you should start with the Build your first .NET MAUI app for Windows tutorial.

Set your environment variable

In order to use the OpenAI SDK, you'll need to set an environment variable with your API key. In this example, we'll use the `OPENAI_API_KEY` environment variable. Once you have your API key from the OpenAI developer dashboard, you can set the environment variable from the command line as follows:

PowerShell

```
setx OPENAI_API_KEY <your-api-key>
```

Note that this method works for development on Windows, but you'll want to use a more secure method for production apps and for mobile support. For example, you can store your API key in a secure key vault that a remote service can access on behalf of your app. See Best practices for OpenAI key safety for more information.

Create a new .NET MAUI project with the required UI elements

We're going to start by creating a new .NET MAUI project in Visual Studio. We'll use the **.NET MAUI App** template and add some UI elements to the **MainPage** to provide users with some recommendations based on a provided location. The UI will have buttons to get recommendations for restaurants, hotels, and attractions.

1. In Visual Studio, create a new **.NET MAUI App** project named **ChatGptRecommendationApp**.

2. Run the new project to make sure the app builds and runs successfully.

3. Open **MainPage.xaml** from the Solution Explorer.

4. Replace the contents of the `VerticalStackLayout` with the following XAML markup:

XAML

```
<Label
    Text="Local AI recommendations"
    SemanticProperties.HeadingLevel="Level1"
    FontSize="32"
    HorizontalOptions="Center" />

<Entry
    x:Name="LocationEntry"
    Placeholder="Enter your location"
    SemanticProperties.Hint="Enter the location for recommendations"
    HorizontalOptions="Center"/>

<Button
    x:Name="RestaurantBtn"
    Text="Get restaurant recommendations"
    SemanticProperties.Hint="Gets restaurant recommendations when you
click"
    Clicked="OnRestaurantClicked"
    HorizontalOptions="Center" />

<Button
    x:Name="HotelBtn"
    Text="Get hotel recommendations"
    SemanticProperties.Hint="Gets hotel recommendations when you click"
    Clicked="OnHotelClicked"
    HorizontalOptions="Center" />

<Button
    x:Name="AttractionBtn"
    Text="Get attraction recommendations"
    SemanticProperties.Hint="Gets attraction recommendations when you
```

```
click"
    Clicked="OnAttractionClicked"
    HorizontalOptions="Center" />

<Label x:Name="SmallLabel"
    Text="Click a button for recommendations!"
    SemanticProperties.HeadingLevel="Level2"
    FontSize="18"
    HorizontalOptions="Center" />
```

5. In order to build the project, you will need to add `Clicked` event handlers for each of the buttons. Add the following code to the **MainPage.xaml.cs** file and remove the existing event handler:

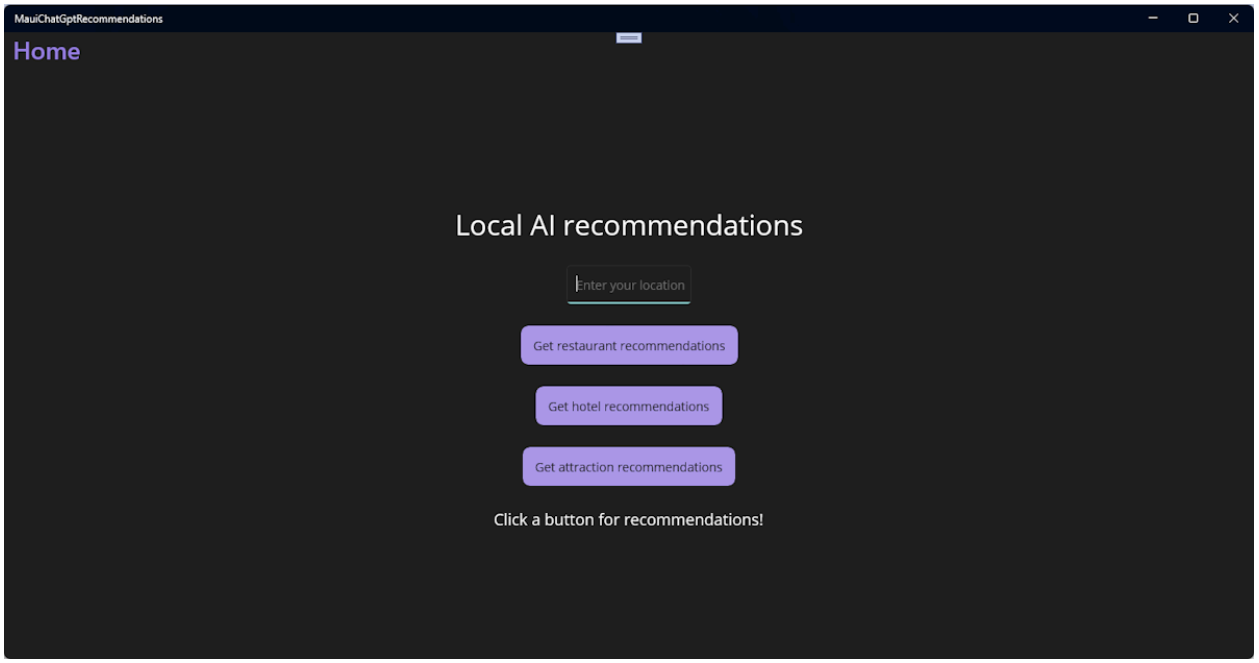
C#

```
private async void OnRestaurantClicked(object sender, EventArgs e)
{
}

private async void OnHotelClicked(object sender, EventArgs e)
{
}

private async void OnAttractionClicked(object sender, EventArgs e)
{
}
```

The event handlers are all marked as `async` because we will be making asynchronous calls to the OpenAI .NET API library. Now when you run the app, you should see the following UI:



Users can enter their location in the `Entry` control and click one of the buttons to get recommendations for restaurants, hotels, or attractions. The `Label` control at the bottom of the UI will display the results.

Next, let's add the **OpenAI** library to the project and get it ready to make some API calls.

Reference and initialize the OpenAI library for .NET

To call OpenAI's ChatGPT APIs, we're going to use a pre-release version of the OpenAI library for .NET NuGet package. This library provides .NET applications with access to the OpenAI REST API. We'll add the library to our project and bootstrap it with our API key.

1. Open the **Package Manager Console** from the **Tools** menu in Visual Studio.
2. Install the OpenAI library by running the following command. The `IncludePrerelease` flag is required because the library is still in preview:

   PowerShell

   ```
   Install-Package OpenAI -IncludePrerelease
   ```

   This should install a pre-release of version 2.0.0 or later to your project. You can also install a specific version of the library by specifying the version number in the command. For example, to install version 2.0.0-beta.4, you would run the following command:

   PowerShell

   ```
   Install-Package OpenAI -Version 2.0.0-beta.4
   ```

3. Open **MainPage.xaml.cs**, the code-behind file for the **MainPage**. Add the following code to the top of the file to reference the OpenAI library and create a variable to hold your OpenAI client. Update the constructor to call the `MainPage_Loaded` method when the page is loaded, and add the `MainPage_Loaded` method to get your OpenAI API key from the Windows registry and initialize the OpenAI client:

   C#

   ```
   private OpenAIClient _chatGptClient;
   ```

```
public MainPage()
{
    InitializeComponent();
    this.Loaded += MainPage_Loaded;
}

private void MainPage_Loaded(object sender, EventArgs e)
{
    var openAiKey =
Environment.GetEnvironmentVariable("OPENAI_API_KEY");

    _chatGptClient = new(openAiKey);
}
```

This will bootstrap the OpenAI library with your API key. You can create your API key on the OpenAI API settings page.

4. In order to compile the project, you will need to add the following `using` statements to the top of the **MainPage.xaml.cs** file:

```
C#

using OpenAI;
using OpenAI.Chat;
using System.ClientModel;
```

Now we're ready to put it all together. In the next section, we'll add some code to the three event handlers to make calls to the OpenAI library and display the recommendation results.

Add ChatGPT API calls and test the app

It's time to add the code to our code-behind file that will use the OpenAI library for .NET to make calls to the OpenAI ChatGPT API. We'll add the code to the three event handlers we created earlier. The code will get the user's location from the `Entry` control and pass it to the API to get recommendations. Then we'll display the results in the `Label` control at the bottom of the UI.

1. Create an `async` method named `GetRecommendationAsync` and call it from each of the event handlers:

```
C#

private async void OnRestaurantClicked(object sender, EventArgs e)
{
    await GetRecommendationAsync("restaurant");
```

```
}

private async void OnHotelClicked(object sender, EventArgs e)
{
    await GetRecommendationAsync("hotel");
}

private async void OnAttractionClicked(object sender, EventArgs e)
{
    await GetRecommendationAsync("attraction");
}

private async Task GetRecommendationAsync(string recommendationType)
{
    if (string.IsNullOrWhiteSpace(LocationEntry.Text))
    {
        await DisplayAlert("Empty location", "Please enter a location
(city or postal code)", "OK");
        return;
    }

    // The model passed to GetChatClient must match an available OpenAI
    // model in your account.
    var client = _chatGptClient.GetChatClient("gpt-3.5-turbo-16k");
    string prompt = $"What is a recommended {recommendationType} near
{LocationEntry.Text}";

    AsyncResultCollection<StreamingChatCompletionUpdate> updates =
client.CompleteChatStreamingAsync(prompt);
    StringWriter responseWriter = new();

    await foreach (StreamingChatCompletionUpdate update in updates)
    {
        foreach (ChatMessageContentPart updatePart in
update.ContentUpdate)
        {
            responseWriter.Write(updatePart.Text);
        }
    }

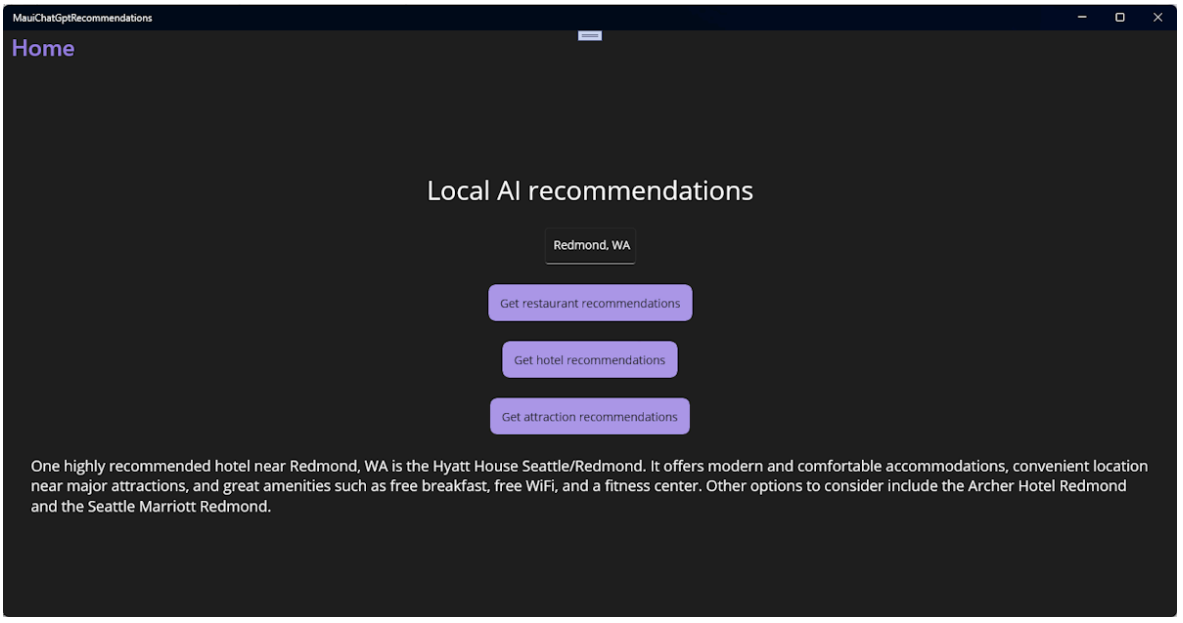
    var returnMessage = responseWriter.ToString();
    SmallLabel.Text = returnMessage;
}
```

This code first checks to make sure the user has entered a location in the `Entry` control. If not, it displays an alert and returns. If the user has entered a location, it gets a `ChatClient` instance and calls the `CompleteChatStreamingAsync` method on the that object to make a call to OpenAI. The `CompleteChatStreamingAsync` method takes a `ChatMessage[]` parameter, which can be provided as a string, as we're doing in the example.

The method returns a `AsyncResultCollection<StreamingChatCompletionUpdate>`, which will stream responses from the API as they're generated. We iterate asynchronously over the `updates` and subsequently iterate over each `ChatMessageContentPart` in the response to build the response string. The response is then displayed in the `SmallLabel` control at the bottom of the UI.

> **Note**
>
> It's' a good idea to add error handling to the `GetRecommendationAsync` method to handle any exceptions that might be thrown by the API call. We've left that out of this example for simplicity.

2. Run the app, enter a location, and test the recommendation buttons. You should see a response from the API in the `Label` control at the bottom of the UI:



That's it! You've successfully created a Windows .NET MAUI app that uses the OpenAI ChatGPT API to provide recommendations for restaurants, hotels, and attractions. Try changing the prompts to see if you can improve the results. You can also try changing the model name passed to `GetChatClient` in `GetRecommendationAsync` to see if you get better results from a different model.

> **Important**
>
> Remember to keep an eye on your API usage after your trial period has expired. You can also set monthly spending limits on your OpenAI account to avoid unexpected charges.

Quickstart: Add DALL-E to your .NET MAUI Windows desktop app

Article • 06/17/2024

In this quickstart, we'll demonstrate how to integrate DALL-E's image generation capabilities into your .NET MAUI Windows desktop app.

Prerequisites

- Visual Studio 2022 17.8 or greater, with the .NET Multi-platform App UI workload installed. For more information, see Installation.
- A functional .NET MAUI project with OpenAI integration into which this capability will be integrated. See *Create a recommendation app with .NET MAUI and ChatGPT* - we'll demonstrate how to integrate DALL-E into the user interface from this how-to.
- An OpenAI API key from your OpenAI developer dashboard.
- A .NET OpenAI NuGet package version 2.0.0 or later installed in your project. This version is currently in pre-release. If you've followed along with the .NET MAUI ChatGPT tutorial, you will have this dependency installed and configured.

What problem will we solve?

You want to add DALL-E's image generation capabilities to your .NET MAUI Windows desktop app to provide users with a rich, interactive experience. They can already use the app to generate text-based recommendations, and you want to add the ability to generate images that visualize an activity in the location they have entered.

Set your environment variable

In order to use the OpenAI SDK, you'll need to set an environment variable with your API key. In this example, we'll use the `OPENAI_API_KEY` environment variable. Once you have your API key from the OpenAI developer dashboard, you can set the environment variable from the command line as follows:

PowerShell

```
setx OPENAI_API_KEY <your-api-key>
```

Note that this method works for development on Windows, but you'll want to use a more secure method for production apps and for mobile support. For example, you can store your API key in a secure key vault that a remote service can access on behalf of your app. See Best practices for OpenAI key safety for more information.

Install and initialize the OpenAI library for .NET

In this section, we'll install the SDK into the .NET MAUI project and initialize it with your OpenAI API key.

1. If you haven't already installed the `OpenAI` NuGet package, you can do so by running `dotnet add package OpenAI -IncludePrerelease` from Visual Studio's terminal window.

2. Once installed, you can initialize the `OpenAIClient` instance from the SDK with your OpenAI API key in `MainPage.xaml.cs` as follows:

```
C#

private OpenAIClient _chatGptClient;

public MainPage()
{
    InitializeComponent();
    this.Loaded += MainPage_Loaded;
}

private void MainPage_Loaded(object sender, EventArgs e)
{
    var openAiKey =
Environment.GetEnvironmentVariable("OPENAI_API_KEY");

    _chatGptClient = new(openAiKey);
}
```

Modify your app's UI

Next, we'll modify the user interface to include an `Image` control that displays a generated image below the recommendation text.

1. If you are are starting with a new project, copy the XAML for `MainPage.xaml` from the Create a recommendation app with .NET MAUI and ChatGPT tutorial.

2. Add a `StackLayout` containing a `Label` control and a `CheckBox` control to `MainPage.xaml` below the `LocationEntry` control to allow users to select whether to generate an image:

```
XML
```

```
...
<Entry
    x:Name="LocationEntry"
    Placeholder="Enter your location"
    SemanticProperties.Hint="Enter the location for recommendations"
    HorizontalOptions="Center"/>

<!-- Add this markup -->
<StackLayout Orientation="Horizontal"
                HorizontalOptions="Center">
    <Label Text="Generate image" VerticalOptions="Center"/>
    <CheckBox x:Name="IncludeImageChk" VerticalOptions="Center"/>
</StackLayout>
...
```

3. Add an `Image` control below the `SmallLabel` control to display the generated image:

```
XML
```

```
...
    <Image x:Name="GeneratedImage"
           WidthRequest="256"
           HeightRequest="256"
           HorizontalOptions="Center"/>
</VerticalStackLayout>
```

Implement DALL-E image generation

In this section, we'll add a method to handle image generation and call it from the existing `GetRecommendationAsync` method to display the generated image.

1. If you are are starting with a new project, make sure your code in `MainPage.xaml.cs` matches the code from the Create a recommendation app with .NET MAUI and ChatGPT tutorial.

2. Add a method named `GetImageAsync` to handle image generation. The new method will call the OpenAI API to generate an image based on the prompt we'll

build in the next step. It returns an `ImageSource` object that is used to display the image in the UI:

```
C#
```

```
public async Task<ImageSource> GetImageAsync(string prompt)
{
    // Use the DALL-E 3 model for image generation.
    ImageClient imageClient = _chatGptClient.GetImageClient("dall-e-
3");

    // Generate an image based on the prompt with a 1024x1024
resolution, the default for DALL-E 3.
    ClientResult<GeneratedImage> response = await
imageClient.GenerateImageAsync(prompt,
        new ImageGenerationOptions
        {
            Size = GeneratedImageSize.W1024xH1024,
            ResponseFormat = GeneratedImageFormat.Uri
        });

    // Image generation responses provide URLs you can use to retrieve
requested image(s).
    Uri imageUri = response.Value.ImageUri;

    return ImageSource.FromUri(imageUri);
}
```

3. Add a using directive for the image generation classes at the top of the file:

```
C#
```

```
using OpenAI.Images;
```

4. Add the following code to the end of the `GetRecommendationAsync` method to conditionally call the `GetImageAsync` method and display the generated image:

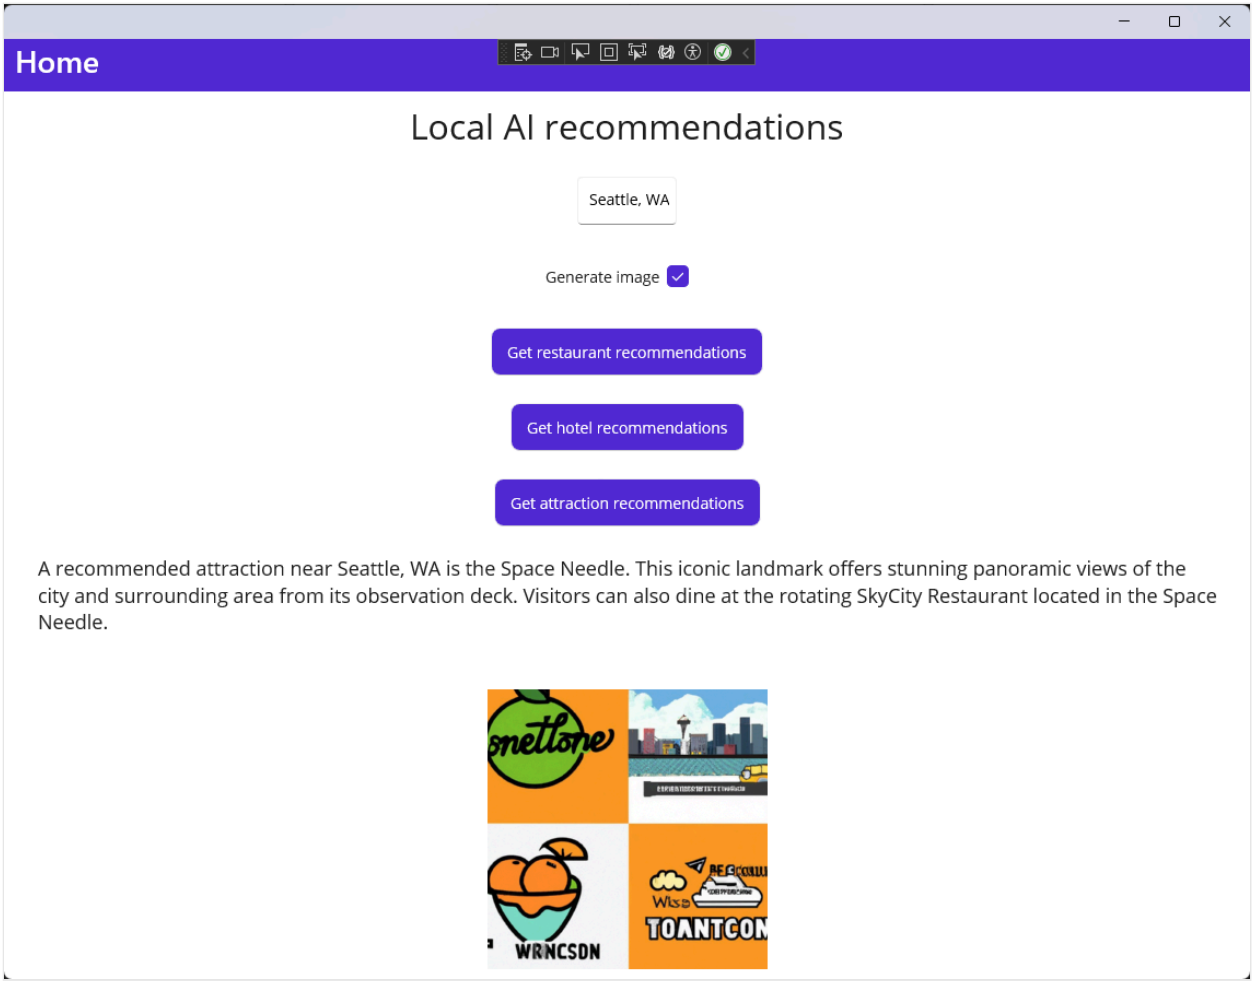
```
C#
```

```
if (IncludeImageChk.IsChecked)
{
    var imagePrompt = $"Show some fun things to do in
{LocationEntry.Text} when visiting a {recommendationType}.";
    GeneratedImage.Source = await GetImageAsync(imagePrompt);
}
```

The `imagePrompt` string is built based on the user's location input and the recommendation type selected.

Run and test

Run your app, enter a valid location, and click one of the recommendation buttons. You should see something like this:



How did we solve the problem?

We added DALL-E's image generation capabilities to our .NET MAUI Windows desktop app. Users can now generate images based on the location they enter and the type of recommendation they select. This provides a rich, interactive experience for users and enhances the app's functionality.

Clean up resources

It's important to make sure your OpenAI account is secure. If you're not planning to use the OpenAI API key for any other projects, you should delete it from your OpenAI developer dashboard. You should also set a reasonable spending limit on your OpenAI account to avoid any unexpected charges. You can check your current usage and spending in the OpenAI dashboard on the Usage page.

Tutorial: Create a .NET MAUI app with C# Markup and the Community Toolkit

Article • 04/27/2023

Build a **.NET MAUI** app with a user interface created without XAML by using **C# Markup** from the .NET MAUI Community Toolkit.

Introduction

The **.NET MAUI Community Toolkit** is a set of extensions, behaviors, animations, and other helpers. One of the features, C# Markup, provides the ability to create a user interface entirely in C# code. In this tutorial, you'll learn how to create a .NET MAUI app for Windows that uses C# Markup to create the user interface.

Setting up the environment

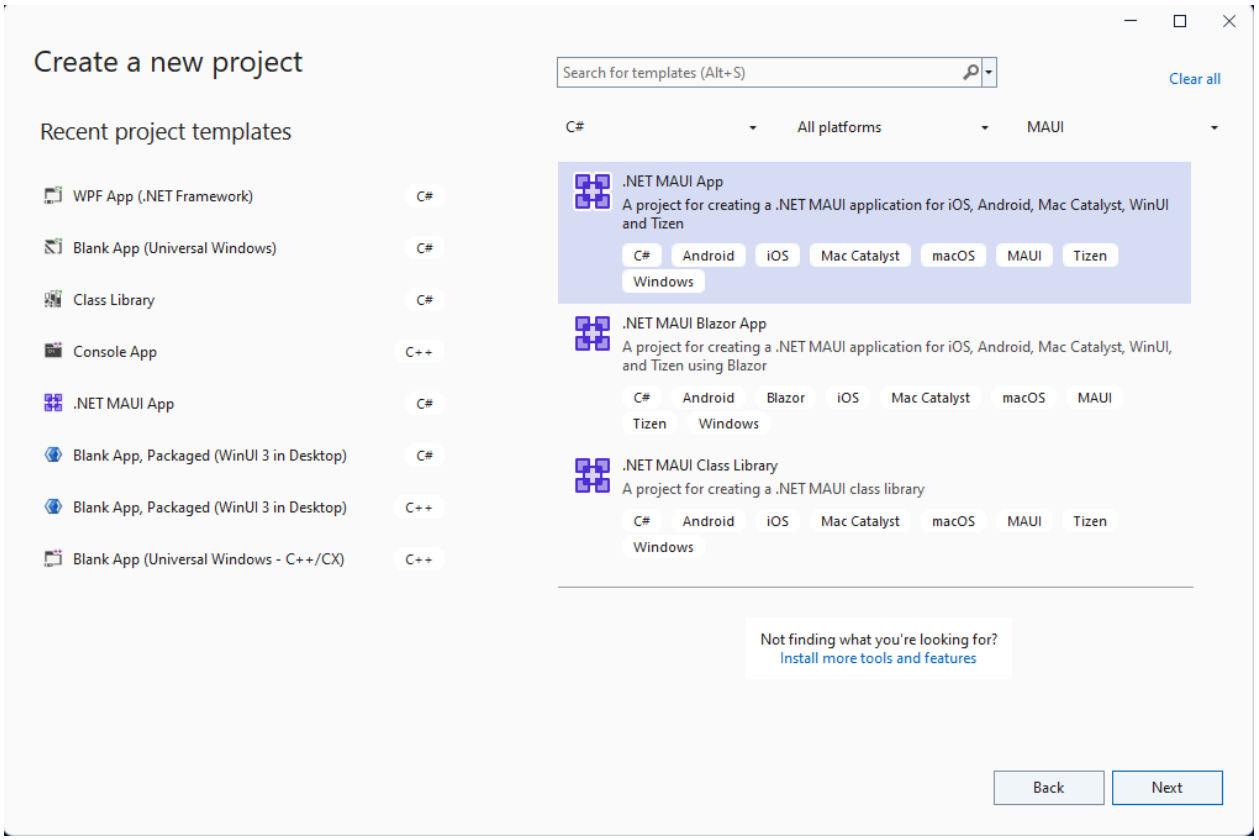
If you haven't already set up your environment for .NET MAUI development, please follow the steps to Get started with .NET MAUI on Windows.

Creating the .NET MAUI project

> ⓘ **Note**
>
> If you are already familiar with setting up a .NET MAUI project, you can skip to the next section.

Launch Visual Studio, and in the start window click **Create a new project** to create a new project.

In the **Create a new project** window, select **MAUI** in the All project types drop-down, select the **.NET MAUI App** template, and click the **Next** button:



Next, on the **Configure your new project** screen, give your project a name, choose a location for it, and click the **Next** button.

On the final screen, **Additional information**, click the **Create** button.

Wait for the project to be created, and for its dependencies to be restored.

In the Visual Studio toolbar, press the **Windows Machine** button to build and run the app. Click the **Click me** button and verify that the button content updates with the number of clicks.

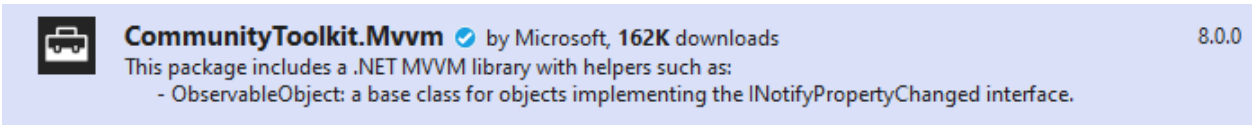
Now that you have verified that the .NET MAUI app on Windows is working as expected, we can integrate the MVVM Toolkit and C# Markup packages. In the next section, you'll add these packages to your new project.

Add C# Markup from the .NET MAUI Community Toolkit

Now that you have your .NET MAUI app running on Windows, let's add a couple of NuGet packages to the project to integrate with the MVVM Toolkit and **C# Markup** from the **.NET MAUI Community Toolkit**.

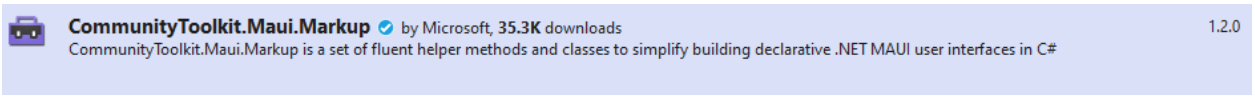
Right-click the project in **Solution Explorer** and select **Manage NuGet Packages...** from the context menu.

In the **NuGet Package Manager** window, select the **Browse** tab and search for **CommunityToolkit.MVVM**:



Add the latest stable version of the **CommunityToolkit.MVVM** package to the project by clicking **Install**.

Next, search for CommunityToolkit.Maui:



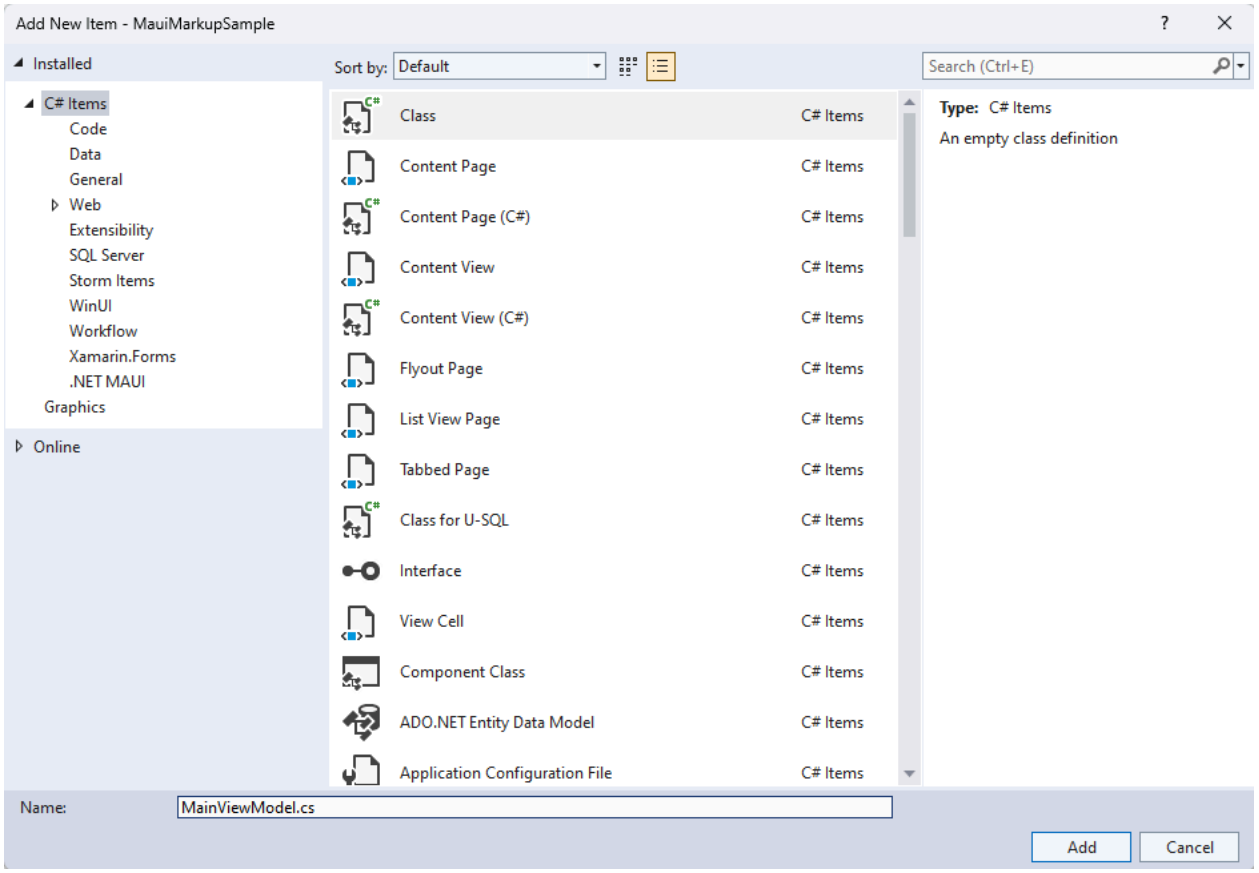
Add the latest stable version of the **CommunityToolkit.Maui.Markup** package to the project by clicking **Install**.

Close the **NuGet Package Manager** window after the new packages have finished installing.

Add a ViewModel to the project

We are going to add a simple **Model-View-ViewModel (MVVM)** implementation with the MVVM Toolkit. Let's start by creating a viewmodel to pair with our view (**MainPage**). Right-click the project again and select **Add | Class** from the context menu.

In the **Add New Item** window that appears, name the class **MainViewModel** and click **Add**:



We are going to leverage the power of the MVVM Toolkit in `MainViewModel`. Replace the contents of the class with the following code:

C#

```
using CommunityToolkit.Mvvm.ComponentModel;
using System.ComponentModel;
using System.Diagnostics;

namespace MauiMarkupSample
{
    [INotifyPropertyChanged]
    public partial class MainViewModel
    {
        [ObservableProperty]
        private string name;
        partial void OnNameChanging(string value)
        {
            Debug.WriteLine($"Name is about to change to {value}");
        }
        partial void OnNameChanged(string value)
        {
            Debug.WriteLine($"Name has changed to {value}");
        }
    }
}
```

If you have completed the Build your first .NET MAUI app for Windows tutorial, you will understand what the code above does. The `MainViewModel` class is decorated with the `INotifyPropertyChanged` attribute, which allows the MVVM Toolkit to generate the `INotifyPropertyChanged` implementation for the class. Marking `MainViewModel` as a `partial class` is required for the .NET source generator to work. The `ObservableProperty` attribute on the `name` private field will add a `Name` property for the class with the proper `INotifyPropertyChanged` implementation in the generated partial class. Adding the `OnNameChanging` and `OnNameChanged` partial methods is optional, but allows you to add custom logic when the `Name` property is changing or has changed.

Build a UI with C# Markup

When building a UI with C# Markup, the first step is to update the `CreateMauiApp()` method in **MauiProgram.cs**. Replace the contents of the method with the following code:

C#

```
public static MauiApp CreateMauiApp()
{
    var builder = MauiApp.CreateBuilder();

    builder
        .UseMauiApp<App>()
        .UseMauiCommunityToolkitMarkup();

    return builder.Build();
}
```

You also need to add a new `using` statement to the top of the file: `using CommunityToolkit.Maui.Markup;`. The call to `UseMauiCommunityToolkitMarkup()` will add the C# Markup support to the app, allowing you to construct your UI with C# code instead of XAML.

The **MainPage.xaml** file will no longer be used when rendering the UI, so you can remove the contents of the `ContentPage`.

XAML

```
<?xml version="1.0" encoding="utf-8" ?>
<ContentPage xmlns="http://schemas.microsoft.com/dotnet/2021/maui"
             xmlns:x="http://schemas.microsoft.com/winfx/2009/xaml"
```

```
             x:Class="MauiMarkupSample.MainPage">
</ContentPage>
```

In **MainPage.xaml.cs**, remove the click event handler and add three private members to the class:

C#

```
private readonly MainViewModel ViewModel = new();
private enum Row { TextEntry }
private enum Column { Description, Input }
```

The `ViewModel` property will create an instance of the `MainViewModel` class to be used when data binding the UI. The `Row` and `Column` enums will be used to define the layout of the UI with C# Markup. It's a simple UI with a single row and two columns which we'll be defining in the next step. You'll also need to add a namespace directive to the top of the file: `using static CommunityToolkit.Maui.Markup.GridRowsColumns;`.

Because the UI elements are going to be defined in the C# code, the `InitializeComponent()` method will not be needed. Remove the call and replace it with the following code to create the UI:

C#

```
public MainPage()
{
    BindingContext = ViewModel;
    Content = new Grid
    {
        RowDefinitions = Rows.Define(
            (Row.TextEntry, 36)),

        ColumnDefinitions = Columns.Define(
            (Column.Description, Star),
            (Column.Input, Stars(2))),

        Children =
        {
            new Label()
                .Text("Customer name:")
                .Row(Row.TextEntry).Column(Column.Description),

            new Entry
            {
                Keyboard = Keyboard.Numeric,
                BackgroundColor = Colors.AliceBlue,
            }.Row(Row.TextEntry).Column(Column.Input)
                .FontSize(15)
                .Placeholder("Enter name")
```

```
                .TextColor(Colors.Black)
                .Height(44)
                .Margin(6, 6)
                .Bind(Entry.TextProperty, nameof(ViewModel.Name),
BindingMode.TwoWay)
        }
    };
}
```

The new code in the `MainPage` constructor is leveraging C# Markup to define the UI. A `Grid` is set as the `Content` of the page. Our new grid defines a row with a height of 36 pixels and two columns with their widths defined using **Star** values, rather than absolute pixel values. The `Input` column will always be twice the width of the `Description` column. The equivalent XAML for these definitions would be:

XAML

```
<Grid.RowDefinitions>
    <RowDefinition Height="36" />
</Grid.RowDefinitions>
<Grid.ColumnDefinitions>
    <ColumnDefinition Width="*" />
    <ColumnDefinition Width="2*" />
</Grid.ColumnDefinitions>
```

The rest of the code to create the grid adds two `Children`, a `Label` and an `Entry`. The `Text`, `Row`, and `Column` properties are set on the `Label` element, and the `Entry` is created with the following properties:

Expand table

Property	Value	Description
`Row`	`Row.TextEntry`	Defines the row number.
`Column`	`Column.Input`	Defines the column number.
`FontSize`	`15`	Sets the font size.
`Placeholder`	`"Enter name"`	Sets the placeholder text to display when the element is empty.
`TextColor`	`Colors.Black`	Sets the text color.
`Height`	`44`	Sets the height of the element.
`Margin`	`6, 6`	Defines the margin around the element.

Property	Value	Description
`Bind`	`Entry.TextProperty, nameof(ViewModel.Name), BindingMode.TwoWay`	Binds the `Text` property of the element to the `Name` property of the view model using two-way data binding.

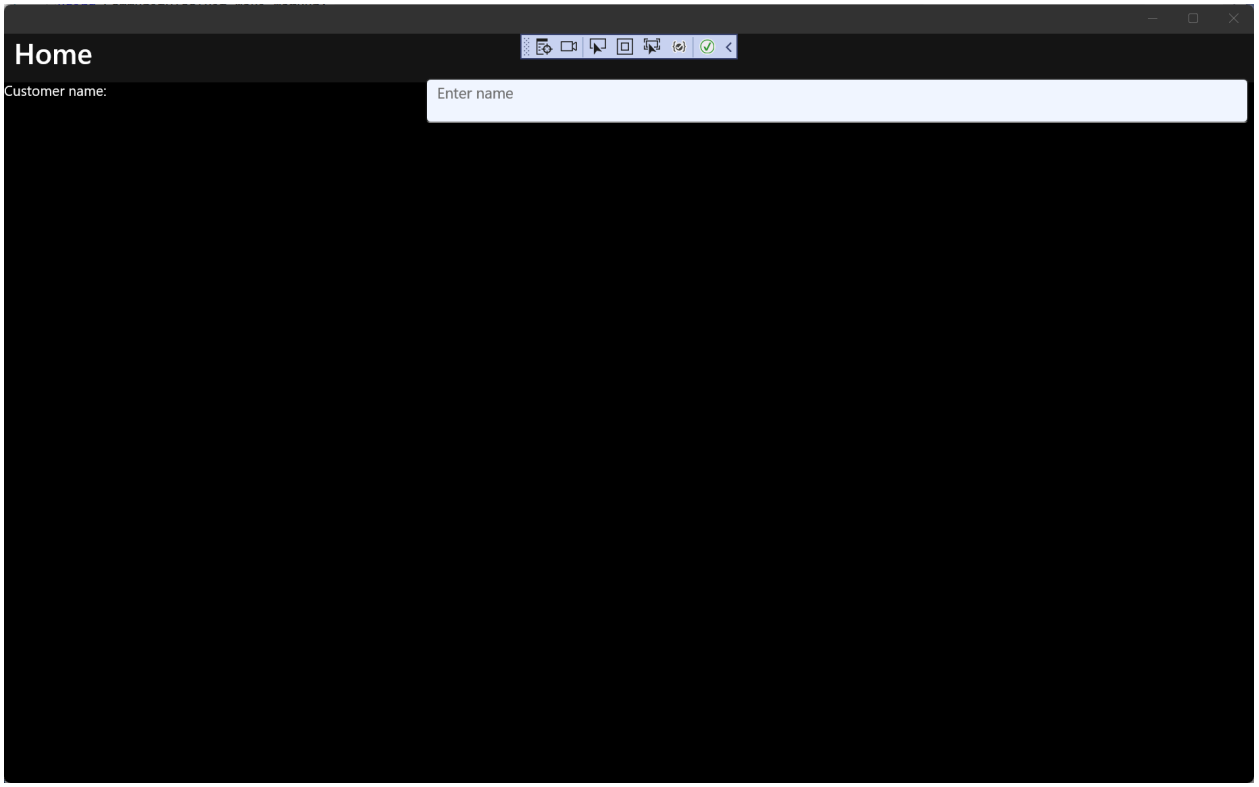
The equivalent XAML to define these child elements would be:

XAML

```
<Label Text="Customer name:"
       Grid.Row="0" Grid.Column="0" />
<Entry Grid.Row="1" Grid.Column="0"
       FontSize="15"
       Placeholder="Enter name"
       HeightRequest="44"
       Margin="6, 6"
       Text="{Binding Path=ViewModel.Name, Mode=TwoWay}" />
```

You may have noticed that the `TextColor` property is not set in the markup above. Setting the `TextColor` of a control requires setting a custom style. For more information about using styles in .NET MAUI, see Style apps using XAML. This is one example where setting properties in C# Markup can be more streamlined than the equivalent XAML. However, using styles in adds ease of reuse and inheritance.

You're now ready to run the app. Press **F5** to build and run the project. The app should look like the following screenshot:



You've now created your first C# Markup app on Windows with .NET MAUI. To learn more about what you can do with C# Markup, see C# Markup documentation.

Migrate from UWP to the Windows App SDK

Article • 09/10/2024

To migrate your app from the Universal Windows Platform (UWP) to the Windows App SDK, your UI code likely needs just a few namespace changes, while much of your platform code can stay the same. You'll need to adjust some code due to differences between UWP apps and desktop apps. But we expect that for most apps (depending on codebase size, of course), migration will take on the order of days rather than weeks.

> **Note**
>
> Your existing UWP app will continue to function as expected. However, to take advantage of modern features in **WinUI 3** and the **Windows App SDK** we recommend migrating your app.

Below are the steps, at a high level, for migrating manually. But see the following section for info about using the .NET Upgrade Assistant tool).

1. Create a new WinUI 3 packaged desktop project (see Create your first WinUI 3 project). That could go into your project's existing solution.
2. Copy your XAML/UI code. In many cases you can simply change namespaces (for example, **Windows.UI.*** to **Microsoft.UI.***).
3. Copy your app logic code. Some APIs need tweaks, such as **Popup**, **Picker**s, and **SecondaryTile**s.

For full details, see the topics in the table below. They describe and demonstrate how to manually migrate your Universal Windows Platform (UWP) application to the Windows App SDK.

Take particular note of What's supported when migrating from UWP to WinUI 3, which describes any functionality that's not yet supported in WinUI 3 and the Windows App SDK. If your app needs any of those features/libraries, then you might want to consider postponing migration.

> **Note**
>
> If your UWP app's source code is written in C++/CX, then also see **Move to C++/WinRT from C++/CX**.

Migrating by using the .NET Upgrade Assistant tool

As a further step in assisting you to migrate your UWP apps to the Windows App SDK and WinUI 3, we've leveraged the .NET Upgrade Assistant, adding support for migrating C# UWP apps. The UWP support automates much of the migration process. For more info, see the topic Migrate from UWP to the Windows App SDK with the .NET Upgrade Assistant.

Containerization benefits

When transitioning to the Windows App SDK, UWP applications might lose the inherent containerization benefits of their original platform. However, those benefits can be restored by using Win32 App Isolation—a new security feature that enhances protection by isolating applications within a sandbox environment. This approach offers additional security against potential threats with minimal changes to your existing code. For more info, and to begin using Win32 App Isolation, see Win32 app isolation overview.

Overall migration strategy

Article • 03/27/2023

Introduction

The Windows App SDK provides a broad set of Windows APIs—with implementations that are decoupled from the OS, and released to developers via NuGet packages. As a developer with a Universal Windows Platform (UWP) application, you can make great use of your existing skill set, and your source code, by moving your app to the Windows App SDK.

With the Windows App SDK you can incorporate the latest runtime, language, and platform features into your app. Since each application is different, and so are your requirements and preferences, there are many different ways to approach the process of migrating your app's source code. But the high-level approach, and code changes needed for various feature areas, are similar. So in this topic we'll review strategies on how you can approach migrating your app, as well as more info (and limitations) about certain feature areas. So also see What's supported when porting from UWP to WinUI 3.

Most Windows Runtime (WinRT) APIs can be used by Windows App SDK apps. But there are some that aren't supported in desktop apps, or have restrictions.

- APIs that have dependencies on UI features that were designed for use only in UWP apps.
- APIs that require package identity. These APIs are supported only in desktop apps that are packaged using MSIX.

For those APIs, we'll show you what alternatives to use. Most of those alternatives are available in WinUI, or via WinRT COM interfaces that are available in the Windows App SDK.

For example, we'll see certain UI scenarios where you'll need to track your main window object, and use various **HWND**-based APIs and interoperation patterns, such as **IInitializeWithWindow::Initialize**.

> **Note**
>
> Also see **Windows Runtime APIs not supported in desktop apps**. Windows App SDK apps are *one* kind of desktop app. Other kinds of desktop app include .NET desktop apps, and C/C++ Win32 desktop apps. The audience of that topic is

developers wishing to migrate to anything in the union of those different kinds of desktop app, including (but not limited to) Windows App SDK apps.

We'd love to hear your feedback about this migration guide, and about your own migration experience. Use the **Feedback** section right at the foot of this page like this:

- For questions and feedback about the Windows App SDK, or just to start a discussion, use the **This product** button. You can also start a discussion on the Discussions tab of the **WindowsAppSDK** GitHub repo. Using those channels, you could also tell us what problem you're trying to solve, how you've tried to solve it so far, and what would be the ideal solution for your app.
- For feedback about missing or incorrect information in this migration guide, use the **This page** button.

Why migrate to the Windows App SDK?

The Windows App SDK offers you an opportunity to enhance your app with new platform features, as well as with the modern Windows UI 3 Library (WinUI 3), which is developed and designed to delight your users.

In addition, the Windows App SDK is backward compatible; it supports apps down to Windows 10, version 1809 (10.0; Build 17763)—also known as the Windows 10 October 2018 Update.

The value proposition of moving the Windows App SDK is manifold. Here are some considerations:

- Latest user interface (UI) platform and controls such as WinUI 3 and WebView2.
- A single API surface across desktop app platforms.
- More frequent release cadence that releases separately from Windows.
- A consistent experience across Windows versions.
- .NET compatibility.
- Backward-compatible down to Windows 10, version 1809.
- Improved runtime environment. See MSIX container.

For more info, see Windows App SDK.

Overview of the migration process

> **Note**

You can think of the UWP version of the app that you want to migrate as the *source* solution/project (it's the *source* of the migration process). The Windows App SDK version is the *target* solution (it's the *target* of the migration process).

Install the Windows App SDK VSIX

Download the Windows App SDK Visual Studio extension (VSIX) installer from Stable release channel for the Windows App SDK, and run to install it.

Create a new project

In Visual Studio, Create your first WinUI 3 project. For example, use the **Blank App, Packaged (WinUI 3 in Desktop)** project template. You can find that project template in the **Create a new project** dialog by choosing language: *C#* or *C++*; platform: *Windows App SDK*; project type: *WinUI* or *Desktop*.

You'll see two projects in **Solution Explorer**—one is qualified as **(Desktop)**, and the other as **(Package)**.

Migrate code with the least dependencies first

To illustrate this recommendation, let's take the PhotoLab case study as an example. For the PhotoLab sample app, one perhaps obvious approach might be to begin by migrating **MainPage**—since that's such an important and prominent piece of the app. But if we were to do that, then we'd soon realize that **MainPage** has a dependency on the **DetailPage** view; and then that **DetailPage** has a dependency on the **Photo** model. If we were to follow that path, then we might be constantly interrupting ourselves (switching over to work on each newly discovered dependency). Certainly we wouldn't expect to get a clean *build* until we'd chased down every dependency, and essentially ported the whole project in one giant leap.

If on the other hand we were to begin with the piece of the project that doesn't depend on anything else, and work outward from there (from least- to most-dependent piece), then we'd be able to focus on each piece one at a time. And we'd also be able to achieve a clean build after migrating each piece, and in that way confirm that the migration process is staying on track.

So when you're migrating your own apps, we recommend that you migrate code with the least dependencies first.

Copy files, or copy file contents?

When you migrate, you will of course be copying over asset *files* (and not asset file *contents*). But what about source code files? As an example let's again take the **MainPage** class from the PhotoLab case study and the Photo Editor case study.

C#. In the C# version (PhotoLab), **MainPage** is made up of the source code files `MainPage.xaml` and `MainPage.xaml.cs`.

C++/WinRT. In the C++/WinRT version (Photo Editor), **MainPage** is made up of the source code files `MainPage.xaml`, `MainPage.idl`, `MainPage.h`, and `MainPage.cpp`.

So you have the choice between these two options:

- (Recommended) you can copy over *the files themselves* (using **File Explorer**), and then add the copies to the target project. Exceptions to this recommendation are files such as `App.xaml` and `App.xaml.cs`, since those files already exist in the target project, and they contain source code that's specific to the Windows App SDK. For those you'll need to *merge* the source code that's already there with source code from the source project.
- Or you can use Visual Studio to create new **Page** files (such as `MainPage.xaml` and `MainPage.xaml.cs`) in the target project, and then copy the *contents* of those source code files over from the source project to the target project. For a C++/WinRT project, this option involves a lot more steps.

Also see the section MainPage and MainWindow.

Folder and file name differences (C++/WinRT)

In a C++/WinRT UWP project, code-behind files for XAML views are named of the form `MainPage.h` and `MainPage.cpp`. But in a C++/WinRT Windows App SDK, you'll need to rename those to `MainPage.xaml.h` and `MainPage.xaml.cpp`.

In a C++/WinRT UWP project, when migrating a hypothetical XAML view (in the sense of models, views, and viewmodels) named **MyPage**, in `MyPage.xaml.cpp` you'll need to add `#include "MyPage.g.cpp"` immediately after `#include "DetailPage.xaml.h"`. And for a hypothetical model named **MyModel**, in `MyModel.cpp` add `#include "MyModel.g.cpp"` immediately after #include "MyModel.h". For an example, see Migrate DetailPage source code.

If you change the name of your migrated project

While migrating, you might choose to give your target project a different name from that of the source project. If you do, then that will affect the default namespace within the source project. As you copy source code over from the source project to the target project, you might need to change namespace names that are mentioned in the source code.

Changing project name (and consequently default namespace name) is something that we do, for example, in the case study A Windows App SDK migration of the UWP PhotoLab sample app (C#). In that case study, instead of copying over file *contents* from the source to the target project, we copy entire files using File Explorer. The source project/namespace name is *PhotoLab*, and the target project/namespace name is *PhotoLabWinUI3*. So we need to search for *PhotoLab* in the contents of any source code files we copied over, and change that to *PhotoLabWinUI3*

In that particular case study, we made those changes in `App.xaml`, `App.xaml.cs`, `MainPage.xaml`, `MainPage.xaml.cs`, `DetailPage.xaml`, `DetailPage.xaml.cs`, `ImageFileInfo.cs`, and `LoadedImageBrush.cs`.

Install the same NuGet packages that were installed in the source project

One task during the migration process is to identify any NuGet packages that the source project has dependencies on. And then install those same NuGet packages in the target project.

For example, in the case study A Windows App SDK migration of the UWP PhotoLab sample app (C#), the source project contains references to the **Microsoft.Graphics.Win2D** NuGet package. So in that case study we add a references to the same NuGet package to the target project.

Mapping UWP features to the Windows App SDK

Article • 03/19/2025

This topic compares major feature areas in the different forms in which they appear in UWP and in the Windows App SDK. The content in this migration guide supports moving from UWP XAML to Windows App SDK XAML—moving to a different UI framework, such as Windows Presentation Foundation (WPF), is outside of the scope of this guidance.

Expand table

Feature	UWP	Windows App SDK (packaged apps)	Migration notes
Packaging	MSIX App has identity	MSIX App has identity	UWP apps migrating to the Windows App SDK should stay on MSIX to ensure trusted clean install and uninstall experience, as well as access to all APIs, including those that require identity.
Container	App container: - security = LowIL - file system access is brokered - no registry access	MSIX Container: - security = MediumIL - file system access same as user, AppData writes virtualized - HKCU registry writes virtualized	Moving to a higher integrity level with the Windows App SDK allows your app to have greater functionality. However, be aware of virtualization if you want to expand the capabilities of your migrated application to write to HKCU or AppData.
Activation and instancing	Package identity + CoreApplication activation, single-instanced by default	Package identity, Main/WinMain + Windows App SDK activation, multi-instanced by default	Ensure your application can handle multi-instance behavior, or use AppInstance to manage your instances.
Lifecycle-managed	Suspend/resume	Power/State notifications	You can use Power/State change notifications to reduce system load.

Feature	UWP	Windows App SDK (packaged apps)	Migration notes
Background tasks	InProc and OOP background tasks	Full trust COM background task implementation	For more info, see Background task migration strategy.
Windowing	CoreWindow, AppWindow (preview)	HWND, AppWindow v2	Windowing behavior has significantly changed in Windows App SDK. See Windowing functionality migration.
Messaging	CoreDispatcher and DispatcherQueue	DispatcherQueue, WndProc	**DispatcherQueue** supports Win32 apps. For additional details on moving from CoreDispatcher to DispatcherQueue see Threading functionality migration.
UI Platform	System XAML, WebView, DirectX, and others	WinUI 3, Webview2, DirectX, and others	For more info, see WinUI migration.
Text-rendering	DirectWrite	DWriteCore	Enables applications to access the latest DWrite features downlevel and receive new DWrite updates separate from the OS release schedule. For more info, see DirectWrite to DWriteCore migration.
Resources	MRT	MRTCore	For more info, see MRT to MRTCore migration.
.NET Runtime	.NET Native / C# 7	.NET 6+/C# 9	The Windows App SDK provides access to the modern .NET runtime, and access to new language features. However, .NET ReadyToRun compilation is not the same as .NET Native, so you should evaluate performance tradeoffs.
2D Graphics	Win2D	Win2D for WinUI 3	We're currently working on a version of Win2D that works with the

Feature	UWP	Windows App SDK (packaged apps)	Migration notes
			Windows App SDK, in progress. See the documentation for more information.
Web authentication	WebAuthenticationBroker	OAuth2Manager	The Windows App SDK provides a new API for OAuth 2.0 functionality. See Implement OAuth functionality in Windows apps for more information.
Windows Runtime components	Windows Runtime component project templates for UWP	- C++: Use the **Windows Runtime Component (WinUI 3)** project template. - C#: Use C#/WinRT to author Windows Runtime Components in a .NET Class Library.	We're currently working on support to Author Windows Runtime Components using C#/WinRT for use in the Windows App SDK and WinUI 3.

What's supported when migrating from UWP to WinUI 3

Article • 03/19/2025

WinUI 3 and the Windows App SDK are new technologies and, when compared to UWP, there are some features that aren't supported. This topic provides information on which features are supported before you attempt migration.

Expand table

UWP feature	WinUI 3 status
Background acrylic	✅ Available via DesktopAcrylicController.
Background tasks	✅ Supported; see BackgroundTaskBuilder (introduced in 1.7).
Common UI controls	✅ Supported
CameraCaptureUI	✅ Supported; see CameraCaptureUI (introduced in 1.7). For alternative APIs, see Using video capture.
Composition/DirectX interop	✅ Most Composition and Drawing features are supported (global composition effects aren't supported in 1.7); see Enhance UI with the Visual layer.
Distributing via Store	✅ Supported
Live Tiles (on Windows 10)	✅ Supported
MapControl	✅ Supported; see MapControl (introduced in 1.5).
MediaElement and MediaPlayerElement	✅ Use MediaPlayerElement, which was introduced in 1.2.
MSAL library	✅ Supported
MSIX	✅ Supported
Single-instancing	✅ Supported
TaskbarManager API	✅ Supported; for details, see TaskbarManager desktop samples.
Toast notifications	✅ Supported
Visual Studio App Center	✅ Supported

UWP feature	WinUI 3 status
WebAuthenticationBroker	✅ Supported; see Microsoft.Security.Authentication.OAuth (introduced in 1.7).
Best launch speed and performance	⚠️ Slight disadvantage, see performance considerations.
CoreTextServicesManager	⚠️ Supported only on Windows 11
PrintManager	⚠️ Supported on Windows 11 (not yet available on Windows 10)
CoreWindow and related APIs	❌ Not supported in 1.7. For alternative APIs with some of the same functionality, see AppWindow, and HWND-based APIs.
Virtual key support for gamepad input	❌ Not supported in 1.7; see Gamepad support in WinUI 3
InkCanvas	❌ Not supported in 1.7
Single-app kiosk	❌ Not supported in 1.7
Xbox and HoloLens	❌ Not supported in 1.7

Performance considerations

Today in version 1.7 of the Windows App SDK, launch speeds, RAM usage, and installation size of WinUI 3 apps are larger/slower than seen in UWP. We're actively working to improve this.

Visual Studio

The **Design** tab of the XAML Designer in Visual Studio (and Blend for Visual Studio) doesn't currently support WinUI 3 projects (as of version 1.7 of the Windows App SDK). For more info, see Create a UI by using XAML Designer.

Mapping UWP APIs and libraries to the Windows App SDK

Article • 06/16/2022

This topic provides a mapping of UWP APIs to their Windows App SDK equivalents. In some cases the mapping isn't one-to-one; either platform might have more or less functionality than the other for a namespace or class.

There are differences in the names of namespaces and classes (including UI controls) between the two platforms. In many cases, it's as easy as changing a namespace name and then your code will compile. Sometimes, a class or API name has changed as well as the namespace name. Other times, the mapping takes a bit more work, and in rare cases requires a change in approach.

How to use the table. First, search for the name of the class member you're using. Members are listed whenever the mapping is more complicated than a simple class name or namespace name change. If your member isn't listed, then search for the name of the class you're using. Classes are listed whenever the mapping is more complicated than simply changing the namespace name (for specific guidance, see the Feature area guides). If your class isn't listed, then the mapping is just a namespace change. So, find your class's namespace name and then you'll find the equivalent Windows App SDK namespace name. Your class will be in that namespace. If your namespace isn't listed, then its name hasn't changed.

Expand table

UWP	Windows App SDK
(**Windows.ApplicationModel.Activation**) LaunchActivatedEventArgs class	(**Microsoft.UI.Xaml**) LaunchActivatedEventArgs class; for example, in **App.OnLaunched**.
(**Windows.ApplicationModel.Background**) BackgroundTaskBuilder class	(**Microsoft.Windows.ApplicationModel.Background**) BackgroundTaskBuilder class. See Using background tasks in Windows apps.
(**Windows.ApplicationModel.Core**) CoreApplication.CreateNewView method	(**Microsoft.UI.Windowing**) AppWindow.Create method
(**Windows.ApplicationModel.Core**) CoreApplicationViewTitleBar class	(**Microsoft.UI.Windowing**) AppWindowTitleBar class
(**Windows.ApplicationModel.Core**) CoreApplicationViewTitleBar.ExtendViewIntoTitleBar property	(**Microsoft.UI.Windowing**) AppWindowTitleBar.ExtendsContentIntoTitleBar property. The platform continues to draw the **Minimize**/**Maximize**/**Close** buttons for you, and reports the occlusion information.

UWP	Windows App SDK
(**Windows.ApplicationModel.Core**) **CoreApplicationViewTitleBar.Height** property	(**Microsoft.UI.Windowing**) **AppWindowTitleBar.Height** property
(**Windows.ApplicationModel.Core**) **CoreApplicationViewTitleBar.SystemOverlayLeftInset** property	(**Microsoft.UI.Windowing**) **AppWindowTitleBar.LeftInset** property
(**Windows.ApplicationModel.Core**) **CoreApplicationViewTitleBar.SystemOverlayRightInset** property	(**Microsoft.UI.Windowing**) **AppWindowTitleBar.RightInset** property
Windows.ApplicationModel.Resources.Core namespace	**Microsoft.Windows.ApplicationModel.Resources**. See MRT to MRT Core migration.
(**Windows.ApplicationModel.Resources.Core**) **ResourceContext.GetForCurrentView** method	(**Microsoft.Windows.ApplicationModel.Resources**) **ResourceManager.CreateResourceContext** method. See ResourceContext.GetForCurrentView, and ResourceContext.GetForViewIndependentUse.
(**Windows.ApplicationModel.Resources.Core**) **ResourceContext.GetForViewIndependentUse** method	(**Microsoft.Windows.ApplicationModel.Resources**) **ResourceManager.CreateResourceContext** method. See ResourceContext.GetForCurrentView, and ResourceContext.GetForViewIndependentUse.
(**Windows.ApplicationModel.Resources.Core**) **ResourceManager.Current** property	Create a new (**Microsoft.Windows.ApplicationModel.Resources**) **ResourceManager** object. See ResourceManager class.
(**Windows.ApplicationModel.Resources.Core**) **ResourceQualifierObservableMap.MapChanged** event	Detect environment changes for yourself. See Resource qualifier value change.
(**Windows.Graphics.Printing**) **PrintManager** class	Not supported in Windows App SDK 1.0.
(**Windows.Media.Capture**) **CameraCaptureUI** class	Not supported in Windows App SDK 1.0.
(**Windows.Security.Authentication.Web**) **WebAuthenticationBroker** class	(**Microsoft.Security.Authentication.OAuth**) OAuth2Manager class (supported in Windows App SDK 1.7 and later). See Implement OAuth functionality in Windows apps for more information on using **OAuth2Manager** and related APIs for performing OAuth 2.0 authentication. See GitHub for a full sample application.
(**Windows.Storage.Pickers**) **FileOpenPicker**, **FileSavePicker**, and **FolderPicker** classes	Supported, but you must use the **IInitializeWithWindow** interface. See MessageDialog, and Pickers.
(**Windows.System.Display**) **DisplayRequest** class	Not supported in Windows App SDK 1.0.
Windows.UI.Composition namespace	**Microsoft.UI.Composition** namespace

UWP	Windows App SDK
(**Windows.UI.Core**) CoreDispatcher class	(**Microsoft.UI.Dispatching**) DispatcherQueue class. See Change CoreDispatcher to DispatcherQueue.
(**Windows.UI.Core**) CoreDispatcher.RunAsync method	(**Microsoft.UI.Dispatching**) DispatcherQueue.TryEnqueue method. See Change RunAsync to TryEnqueue.
(**Windows.UI.Core**) CoreWindow class	(**Microsoft.UI.Windowing**) AppWindow class. See Windowing functionality migration.
(**Windows.UI.Core**) CoreWindow.Bounds property (commonly appears in C# as `CoreWindow.GetForCurrentThread.Bounds`)	(**Microsoft.UI.Windowing**) AppWindow.Size property
(**Windows.UI.Core**) CoreWindow.GetForCurrentThread method	No direct 1:1 mapping to a Windows App SDK API. When using XAML, you can get **Window.AppWindow** to get the **AppWindow** associated with a XAML **Window**, but an app needs to cache the **Window** or **AppWindow** if it wants to access it from somewhere that doesn't otherwise have access. We recommend caching and exposing the **Window** on the **App** object.
(**Windows.UI.Core**) CoreWindow.Activate method	(**Microsoft.UI.Windowing**) AppWindow.Show method
(**Windows.UI.Core**) CoreWindow.Dispatcher property	(**Microsoft.UI.Xaml**) Window.DispatcherQueue property. See Change CoreWindow.Dispatcher to Window.DispatcherQueue.
(**Windows.UI.Core**) CoreWindow.SizeChanged event	(**Microsoft.UI.Windowing**) AppWindowChangedEventArgs.DidSizeChange method
(**Windows.UI.Core**) SystemNavigationManager class (global back button)	Not supported. Implement a back button within your own UI. See A Windows App SDK migration of the UWP PhotoLab sample app (C#).
(**Windows.UI.Core**) WindowSizeChangedEventArgs class	(**Microsoft.UI.Xaml**) WindowSizeChangedEventArgs class; for example, in a handler for (**Microsoft.UI.Xaml**) Window.SizeChanged.
(**Windows.UI.Popups**) MessageDialog class	Supported, but you must use the IInitializeWithWindow interface. See MessageDialog, and Pickers.
(**Windows.UI.Text.Core**) CoreTextServicesManager class	Supported only on Windows 11.
(**Windows.UI.ViewManagement**) AccessibilitySettings.HighContrastChanged event	(**Microsoft.UI.System**) ThemeSettings.Changed event

UWP	Windows App SDK
(Windows.UI.ViewManagement) ApplicationView class	(Microsoft.UI.Windowing) AppWindow class
(Windows.UI.ViewManagement) ApplicationView.Title property	(Microsoft.UI.Windowing) AppWindow.Title property
(Windows.UI.ViewManagement) ApplicationView.TryConsolidateAsync method	(Microsoft.UI.Windowing) AppWindow.Destroy method
(Windows.UI.ViewManagement) ApplicationView.TryEnterFullScreenMode method	(Microsoft.UI.Windowing) AppWindow.SetPresenter method with AppWindowPresenterKind.FullScreen
(Windows.UI.ViewManagement) ApplicationView.TryEnterViewModeAsync method with ApplicationViewMode.CompactOverlay	(Microsoft.UI.Windowing) AppWindow.SetPresenter method with AppWindowPresenterKind.CompactOverlay
(Windows.UI.ViewManagement) ApplicationView.TryResizeView method	(Microsoft.UI.Windowing) AppWindow.Resize method
(Windows.UI.ViewManagement) ApplicationViewMode.CompactOverlay field	(Microsoft.UI.Windowing) AppWindowPresenterKind.CompactOverlay field
(Windows.UI.ViewManagement) ApplicationViewTitleBar class	(Microsoft.UI.Windowing) AppWindowTitleBar class
(Windows.UI.ViewManagement) ApplicationViewWindowingMode.FullScreen field	(Microsoft.UI.Windowing) AppWindowPresenterKind.FullScreen field
(Windows.UI.WindowManagement) AppWindow class	(Microsoft.UI.Windowing) AppWindow class
(Windows.UI.WindowManagement) AppWindow.Changed event	(Microsoft.UI.Windowing) Microsoft.UI.Windowing.AppWindow.Changed event
(Windows.UI.WindowManagement) AppWindow.CloseAsync method	(Microsoft.UI.Windowing) AppWindow.Destroy method
(Windows.UI.WindowManagement) AppWindow.GetPlacement method	(Microsoft.UI.Windowing) AppWindow.Position property
(Windows.UI.WindowManagement) Appwindow.RequestMoveXxx methods	(Microsoft.UI.Windowing) AppWindow.Move method
(Windows.UI.WindowManagement) AppWindow.RequestSize method	(Microsoft.UI.Windowing) AppWindow.Resize method
(Windows.UI.WindowManagement) AppWindow.Title property	(Microsoft.UI.Windowing) AppWindow.Title property
(Windows.UI.WindowManagement) AppWindow.TryCreateAsync method	(Microsoft.UI.Windowing) AppWindow.Create method

UWP	Windows App SDK
(**Windows.UI.WindowManagement**) AppWindow.TryShowAsync method	(**Microsoft.UI.Windowing**) AppWindow.Show method

Overview of feature area guides

Article • 03/19/2025

A collection of migration guidance topics, each focusing on a specific feature area.

Feature area guides in this section

Expand table

Topic	Description
User interface migration (including WinUI 3)	This topic shows how to migrate your user interface (UI) code, including migrating to WinUI 3.
Windowing functionality migration	This topic contains guidance related to window management, including migrating from UWP's **ApplicationView**/**CoreWindow** or **AppWindow** to the Window App SDK **Microsoft.UI.Windowing.AppWindow**.
Application lifecycle functionality migration	This topic contains migration guidance in the application lifecycle feature area.
Toast notifications functionality migration	This topic contains migration guidance in the toast notifications feature area.
Push notifications functionality migration	This topic contains migration guidance in the push notifications feature area.
DirectWrite to DWriteCore migration	DWriteCore is the Windows App SDK implementation of DirectWrite.
MRT to MRT Core migration	This topic contains guidance for migrating from UWP's Resource Management System (also known as MRT) to the Windows App SDK's MRT Core.
Threading functionality migration	This topic shows how to migrate your threading code.
Background task migration strategy	This topic contains considerations and strategies for approaching the migration process, and how to migrate your UWP background tasks to use the Windows App SDK background task APIs.

User interface migration (including WinUI 3)

Article • 03/27/2023

This topic shows how to migrate your user interface (UI) code, including migrating to WinUI 3.

Summary of API and/or feature differences

The **Window.Current** property migrates to **App.Window**. And the **CoreDispatcher.RunAsync** method migrates to **DispatcherQueue.TryEnqueue**.

You need to set your window's *handle* (**HWND**) on a **MessageDialog**, and on **Picker**s.

To use **DataTransferManager** APIs, you need to associate them with your window.

For **ContentDialog** and **Popup**, you need to set their XamlRoot property.

You may need to refactor your Visual State Manager and **Page.Resources** XAML markup.

In the Windows App SDK, the **AcrylicBrush** always samples from the app content.

Change Windows.UI.Xaml.Window.Current to App.Window

This section applies if you're using the **Windows.UI.Xaml.Window.Current** property in your UWP app. That property isn't supported in the Windows App SDK, so this section describes how to port UWP code that uses **Window.Current**.

C#

```
// MainPage.xaml.cs in a UWP app
var width = Window.Current.Bounds.Width;
```

Your Windows App SDK app can add its own notion of a *current*, or *main* window by using a public static property on your **App** class.

C#

```
// App.xaml.cs in a Windows App SDK app
public partial class App : Application
```

```
{
    ...
    public static Window Window { get { return m_window; } }
    private static Window m_window;
}
```

Then, within the **App** class itself, you can change `Window.Current` to simply `window`. Outside of the **App** class, change `Window.Current` to `App.Window`, like this:

C#

```
// MainPage.xaml.cs in a UWP app
var width = App.Window.Bounds.Width;
```

MessageDialog, and Pickers

In your UWP app, if you use certain types from the **Windows.UI.Popups** or **Windows.Storage.Pickers** namespaces, then this section contains info to help you migrate that code. The code examples below use **MessageDialog**, but you can apply exactly the same techniques to displaying a picker (for example, a **FileOpenPicker**, a **FileSavePicker**, or a **FolderPicker**).

The steps that you have to follow in a desktop app are described in Display WinRT UI objects that depend on CoreWindow.

> **Note**
>
> For new apps, we recommend using the ContentDialog control instead of MessageDialog. For more info, see the ContentDialog, and Popup section below.

Here's some typical UWP code to display a **MessageDialog**.

C#

```
// In a UWP app
var showDialog = new Windows.UI.Popups.MessageDialog("Message here");
await showDialog.ShowAsync();
```

And here's the equivalent code in a Windows App SDK app.

C#

```
// MainWindow.xaml.cs in a WinUI 3 app
var showDialog = new Windows.UI.Popups.MessageDialog("Message here");
WinRT.Interop.InitializeWithWindow.Initialize(showDialog,
    WinRT.Interop.WindowNative.GetWindowHandle(this));
await showDialog.ShowAsync();
```

DataTransferManager

In your UWP app, if you call the **DataTransferManager.ShowShareUI** method, then this section contains info to help you migrate that code.

Here's some typical UWP code that calls **ShowShareUI**.

C#

```
// In a UWP app
var dataTransferManager =
Windows.ApplicationModel.DataTransfer.DataTransferManager.GetForCurrentView(
);

dataTransferManager.DataRequested += (sender, args) =>
{
    args.Request.Data.Properties.Title = "In a UWP app...";
    args.Request.Data.SetText("...display the user interface for sharing
content with another app.");
    args.Request.Data.RequestedOperation =
        Windows.ApplicationModel.DataTransfer.DataPackageOperation.Copy;
};

Windows.ApplicationModel.DataTransfer.DataTransferManager.ShowShareUI();
```

To use **DataTransferManager.ShowShareUI** in your Windows App SDK app, you need to associate the Share UI with your window. And that needs to be done manually. For more info, and code examples, see Display WinRT UI objects that depend on CoreWindow.

ContentDialog, and Popup

If in your UWP app you're using the **Windows.UI.Xaml.Controls.ContentDialog** or **Windows.UI.Xaml.Controls.Primitives.Popup** classes, then this section contains info to help you migrate that code. The code examples below use **ContentDialog**, but you can apply exactly the same techniques to displaying a **Popup** object.

Here's some typical UWP code to display a **ContentDialog**.

C#

```
// MainPage.xaml.cs in a UWP app
var unsupportedFilesDialog = new ContentDialog();
// Set Title, Content, etc.
await unsupportedFilesDialog.ShowAsync();
```

In your Windows App SDK app, you just need to also set the dialog's XamlRoot property. Here's how.

C#

```
// MainPage.xaml.cs in a Windows App SDK app
var unsupportedFilesDialog = new ContentDialog();
// Set Title, Content, etc.
unsupportedFilesDialog.XamlRoot = this.Content.XamlRoot;
await unsupportedFilesDialog.ShowAsync();
```

Do I need to implement page navigation?

In a UWP project, by default there will be navigation code in the methods of the **App** class, even if your app is simple enough that it has only one **Page**.

When you create a new Windows App SDK project in Visual Studio, the project template provides you with a **MainWindow** class (of type **Microsoft.UI.Xaml.Window**), but no **Page**. And the project template doesn't provide any navigation code.

For a Windows App SDK app that's simple enough (a single-page app), you might be able to simplify it. It might be that you needn't create pages or user controls in your Windows App SDK project—but instead copy the XAML markup and code-behind of that single page into **MainWindow**. However, there are some things that **MainWindow** doesn't support. **Window** isn't a DependencyObject, so capabilities such as **Resources** and **DataContext** don't exist on it. Neither do events such as **Load** and **Unload**. For more info, and workarounds, see Visual State Manager, and Page.Resources.

If on the other hand you want or need navigation between pages in your Windows App SDK app, then you can do so by migrating the **App.OnLaunched** and **App::OnNavigationFailed** methods from your UWP app. In **App.OnLaunched**, locate the navigation code (the code that creates *rootFrame*, and navigates to the first page of your app) and merge it right in between the two existing lines of code (the lines that create a window and then activate it). You'll also need to migrate the code you've copy-pasted. For a simple code example, see **Page class**.

Visual State Manager, and Page.Resources

Also see Do I need to implement page navigation?. If you *do* have a UWP app that's simple enough where you can copy your XAML markup and code-behind into **MainWindow**, then bear in mind these exceptions.

Your **MainWindow** class (of type **Microsoft.UI.Xaml.Window**) isn't a control, so it doesn't support Visual State Manager XAML markup and code-behind (see Tutorial: Create adaptive layouts). You have these two options, though:

- Add a **UserControl** item to the project, and migrate your markup and code-behind to that. Then place an instance of that user control in **MainWindow**.
- Add a **Page** item to the project, and migrate your markup and code-behind to that. Then add code to your **App** class to navigate to that **Page** on startup, as described in Do I need to implement page navigation?.

In addition, you won't be able to copy a `<Page.Resources>` element over to **MainWindow** and just rename it to `<Window.Resources>`. Instead, parent the **Resources** element under the root layout container (for example, a **Grid**) in the XAML markup for **MainWindow**. That will look like this:

XAML

```
<Window ...>
    <Grid>
        <Grid.Resources>...</Grid.Resources>
        ...
    </Grid>
</Window>
```

AcrylicBrush.BackgroundSource property

The **AcrylicBrush.BackgroundSource** property exists in UWP, but not in the Windows App SDK. In the Windows App SDK, the **AcrylicBrush** always samples from the app content.

So if you're accessing the **AcrylicBrush.BackgroundSource** property in the source code of your UWP app (whether that's in XAML markup or in imperative code), then remove that code when migrating your app to the Windows App SDK. Instead, use the DesktopAcrylicController class.

Keyboard API and events parity between UWP and WinUI 3

Article • 09/25/2024

The migration of apps from the Universal Windows Platform (UWP) to the Windows App SDK (specifically, WinUI 3) might require a few changes in the way input keyboard events are handled, primarily due to the app model differences. This topic describes commonly identified differences.

By using **UIElement**-specific WinUI 3 event handlers, and developing custom solutions for event routing, you can easily transition your apps to modern Windows applications.

Mapping to WinUI 3 APIs from UWP APIs

UWP APIs

In UWP, **CoreWindow** serves as the fundamental component attached directly to each application window, handling global input events across the application. In this topic, some of the commonly used events in conjunction with **CoreWindow** are discussed:

- **KeyDown**. Event raised by any key press when the app window has focus.
- **KeyUp**. Event raised when any key is released.
- **CharacterReceived**. Event raised when a new character is received by the input queue.
- **CoreDispatcher.AcceleratorKeyActivated**. Event raised when an accelerator key is activated (either pressed or held down).

C#

```
public sealed partial class MainPage : Page
{
    public MainPage()
    {
        this.InitializeComponent();
        var coreWindow = CoreWindow.GetForCurrentThread();
        coreWindow.KeyDown += CoreWindow_KeyDown;
        coreWindow.KeyUp += CoreWindow_KeyUp;
        coreWindow.CharacterReceived += CoreWindow_CharacterReceived;
        coreWindow.Dispatcher.AcceleratorKeyActivated +=
Dispatcher_AcceleratorKeyActivated;
    }

    private void CoreWindow_KeyDown(CoreWindow sender, KeyEventArgs args)
```

```
    {
        System.Diagnostics.Debug.WriteLine($"KeyDown: {args.VirtualKey}");
    }
    private void CoreWindow_KeyUp(CoreWindow sender, KeyEventArgs args)
    {
        System.Diagnostics.Debug.WriteLine($"KeyUp: {args.VirtualKey}");
    }

    private void CoreWindow_CharacterReceived(CoreWindow sender,
CharacterReceivedEventArgs args)
    {
        System.Diagnostics.Debug.WriteLine($"CharacterReceived:
{(char)args.KeyCode}");
    }

    private void Dispatcher_AcceleratorKeyActivated(CoreDispatcher sender,
AcceleratorKeyEventArgs args)
    {
        if (args.EventType == CoreAcceleratorKeyEventType.KeyDown)
        {
            bool isCtrlPressed =
(Window.Current.CoreWindow.GetKeyState(VirtualKey.Control) &
CoreVirtualKeyStates.Down) ==
            CoreVirtualKeyStates.Down;
            if (isCtrlPressed && args.VirtualKey == VirtualKey.C)
            {
                System.Diagnostics.Debug.WriteLine("Ctrl+C Pressed");
            }
            else if (args.VirtualKey == VirtualKey.F1)
            {
                System.Diagnostics.Debug.WriteLine("F1 Key Pressed");
            }
        }
    }
}
```

WinUI 3 APIs (Windows App SDK)

WinUI 3 (Windows App SDK) has a different concept from **CoreWindow**. Instead, WinUI 3 provides an input event handling mechanism using **Microsoft.Ui.Xaml.UIElement** (UIElement). Each class that inherits from **UIElement** can implement various keyboard or pointer events (which are also present in UWP's **CoreWindow**) such as **KeyUp**, **KeyDown**, **CharacterReceived**, and others. This approach allows event handling at the level of a specific UI control.

For detailed info about event handling, see Keyboard events. You can associate keyboard events either XAML or in imperative source code. These examples demonstrate key event handling through code and accelerator key events in XAML.

XAML

```
<Window
    x:Class="SampleApp.MainWindow"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:SampleApp"
    xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
    xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
    mc:Ignorable="d">

    <StackPanel Orientation="Horizontal" x:Name="stackPanelControl"
HorizontalAlignment="Center" VerticalAlignment="Center">
        <Button x:Name="myButton" Click="myButton_Click">Click Me</Button>
        <StackPanel.KeyboardAccelerators>
            <KeyboardAccelerator Key="C" Modifiers="Control"
Invoked="OnCtrlCInvoked"/>
        </StackPanel.KeyboardAccelerators>
    </StackPanel>
</Window>
```

C#

```
public sealed partial class MainWindow : Window
{
    public MainWindow()
    {
        this.InitializeComponent();
        stackPanelControl.KeyDown += OnKeyDownHandler;
        stackPanelControl.KeyUp += OnKeyUpHandler;
        stackPanelControl.CharacterReceived += OnCharacterReceivedHandler;
    }

    private void myButton_Click(object sender, RoutedEventArgs e)
    {
        myButton.Content = "Clicked";
    }

    private void OnKeyDownHandler(object sender, KeyRoutedEventArgs e)
    {
        System.Diagnostics.Debug.WriteLine($"KeyDown: {e.Key}");
    }

    private void OnKeyUpHandler(object sender, KeyRoutedEventArgs e)
    {
        System.Diagnostics.Debug.WriteLine($"KeyUp: {e.Key}");
    }

    private void OnCharacterReceivedHandler(UIElement sender,
CharacterReceivedRoutedEventArgs args)
    {
        System.Diagnostics.Debug.WriteLine($"CharacterReceived:
{(char)args.Character}");
```

```
    }

    private void OnCtrlCInvoked(KeyboardAccelerator sender,
KeyboardAcceleratorInvokedEventArgs args)
    {
        if (args.KeyboardAccelerator.Key == VirtualKey.C &&
args.KeyboardAccelerator.Modifiers == VirtualKeyModifiers.Control)
        {
            System.Diagnostics.Debug.WriteLine("Ctrl+C Pressed");
            args.Handled = true;
        }
    }
}
```

Windowing functionality migration

Article • 04/05/2023

This topic contains guidance related to window management, including migrating from UWP's ApplicationView/CoreWindow or AppWindow to the Window App SDK Microsoft.UI.Windowing.AppWindow.

Important APIs

- Microsoft.UI.Windowing.AppWindow
- Windows.UI.Core.CoreWindow.Dispatcher property
- Microsoft.UI.Window.DispatcherQueue property

Summary of API and/or feature differences

The Windows App SDK provides a Microsoft.UI.Windowing.AppWindow class that's based on the Win32 HWND model. That **AppWindow** class is the Windows App SDK's version of UWP's ApplicationView/CoreWindow and AppWindow.

To take advantage of the Windows App SDK windowing APIs means that you'll migrate your UWP code to use the Win32 model. For more info about the Windows App SDK **AppWindow**, see Manage app windows.

> **Tip**
>
> The **Manage app windows** topic contains a code example demonstrating how to retrieve an **AppWindow** from a WinUI 3 window. In your WinUI 3 app, use that code pattern so that you can call the **AppWindow** APIs mentioned in the rest of this topic.

Window types in UWP versus the Windows App SDK

In a UWP app, you can host window content using ApplicationView/CoreWindow, or AppWindow. The work involved in migrating that code to the Windows App SDK depends on which of those two windowing models your UWP app uses. If you're familiar with UWP's Windows.UI.WindowManagement.AppWindow, then you might see similarities between that and Microsoft.UI.Windowing.AppWindow.

UWP window types

- Windows.UI.ViewManagement.ApplicationView/Windows.UI.Core.CoreWindow.
- Windows.UI.WindowManagement.AppWindow. **AppWindow** consolidates the UI thread and the window that the app uses to display content. UWP apps that use **AppWindow** will have less work to do than **ApplicationView**/**CoreWindow** apps to migrate to the Windows App SDK **AppWindow**.

Windows App SDK window type

- Microsoft.UI.Windowing.AppWindow is the high-level abstraction of a system-managed container of the content of an app.

Keep in mind that the differences in windowing models between UWP and Win32 mean that there's not a direct 1:1 mapping between the UWP API surface and the Windows App SDK API surface. Even for class and member names that *do* carry over from UWP (reflected in this topic's mapping tables), behavior might also differ.

Splash screens

Unlike UWP apps, Win32 apps don't by default show a splash screen on launch. UWP apps relying on this feature for their launch experience might choose to implement a custom transition to their first app window.

Create, show, close, and destroy a window

The lifetime of a Microsoft.UI.Windowing.AppWindow is the same as for an HWND; meaning that the **AppWindow** object is available immediately after the window has been created, and is destroyed when the window is closed.

Create and show

AppWindow.Create creates an app window with the default configuration. Creating and showing a window is only necessary for scenarios where you're not working with a UI framework. If you're migrating your UWP app to a Win32-compatible UI framework, then you can still reach your **AppWindow** object from an already-created window by using the windowing interop methods.

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
CoreApplication.CreateNewView or CoreWindow.GetForCurrentThread	AppWindow.TryCreateAsync	AppWindow.Create
CoreWindow.Activate	AppWindow.TryShowAsync	AppWindow.Show

Close

In UWP, ApplicationView.TryConsolidateAsync is the programmatic equivalent of the user initiating a close gesture. This concept of *consolidation* (in UWP's **ApplicationView/CoreWindow** windowing model) doesn't exist in Win32. Win32 doesn't require that windows exist in separate threads. Replicating the UWP's **ApplicationView/CoreWindow** windowing model would require the developer to create a new thread, and create a new window there. Under the Win32 model, the default system behavior is **Close** > **Hide** > **Destroy**.

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
ApplicationView.TryConsolidateAsync	AppWindow.CloseAsync	AppWindow.Destroy

Basic window customization

As you migrate from UWP to the Windows App SDK, you can expect the same experience from your default **AppWindow**. But if needed, you can change the default **Microsoft.UI.Windowing.AppWindow** for customized windowing experiences. See Microsoft.UI.Windowing.AppWindow for more info on how to customize your windows.

Resizing a window

Expand table

Window title

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
ApplicationView.Title	AppWindow.Title	AppWindow.Title

Compact overlay, and full-screen

Apps that enter into compact overlay, or full-screen, should take advantage of the Windows App SDK AppWindowPresenter. If you're familiar with the UWP **AppWindow**, then you might already be familiar with the concept of presenters.

There isn't a 1:1 mapping of functionality and behavior from UWP app window presenters to Windows App SDK app window presenters. If you have a UWP **ApplicationView/CoreWindow** app, then you can still have compact overlay (picture-in-picture) or full-screen windowing experiences in your app, but the concept of presenters might be new to you. For more information on app window presenters, see Presenters. By default, an overlapped presenter is applied to an **AppWindow** at creation time. **CompactOverlay** and **FullScreen** are the only available presenters, aside from default.

Compact overlay

If you used UWP's **ApplicationViewMode** or **AppWindowPresentionKind** to present a compact overlay window, then you should use the compact overlay **AppWindowPresenterKind**. The Microsoft.UI.Windowing.CompactOverlayPresenter supports only three fixed window sizes at a 16:9 aspect ratio, and can't be resized by the user. Instead of **ApplicationViewMode.TryEnterViewModeAsync** or **AppWindowPresenterKind.RequestPresentation**, you should use AppWindow.SetPresenter to change the presentation of the **AppWindow**.

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
ApplicationViewMode.CompactOverlay	AppWindowPresentationKind.CompactOverlay	AppWindowPresenterKind.CompactOverlay
ApplicationView.TryEnterViewModeAsync with	AppWindowPresenter.RequestPresentation with	AppWindow.SetPresenter with **AppWindowPresenterKind.CompactOverlay**

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
ApplicationViewMode.CompactOverlay	AppWindowPresenterKind.CompactOverlay	

Full-screen

If you used UWP's **ApplicationViewWindowingMode** or **AppWindowPresentionKind** classes to present a full-screen window, then you should use the full-screen **AppWindowPresenterKind**. The Windows App SDK supports only the most restrictive full-screen experience (that is, when **FullScreen** is **IsExclusive**). For **ApplicationView/CoreWindow**, you can use the **ApplicationView.ExitFullScreenMode** to take the app out of full-screen. When using presenters, you can take an app out of full-screen by setting the presenter back to overlapped/default by using **AppWindow.SetPresenter**.

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
ApplicationViewWindowingMode.FullScreen	AppWindowPresentationKind.FullScreen	AppWindowPresenterKind.FullScreen
ApplicationView.TryEnterFullScreenMode	AppWindowPresenter.RequestPresentation with **AppWindowPresenterKind.FullScreen**	AppWindow.SetPresenter with **AppWindowPresenterKind.FullScreen**

For more details on how to work with app window presenters, see the Windowing gallery sample. It demonstrates how to toggle different app window presenter states.

Custom title bar

> **Note**
>
> Title bar customization APIs currently work on Windows 11 only. We recommend that you check AppWindowTitleBar.IsCustomizationSupported in your code before you call these APIs.

If your app uses a default title bar, then there's no additional title bar work needed when you migrate to Win32. If on the other hand your UWP app has a custom title bar, then it's possible to recreate the following scenarios in your Windows App SDK app.

1. Customize the system-drawn title bar
2. App-drawn custom title bar

Code that uses the UWP **ApplicationViewTitleBar**, **CoreApplicationViewTitleBar**, and **AppWindowTitleBar** classes migrates to using the Windows App SDK **Microsoft.UI.Windowing.AppWindowTitleBar** class.

Customize the system-drawn title bar

Here's a table of the color customization APIs.

> **Note**
>
> When AppWindowTitleBar.ExtendsContentIntoTitleBar is `true`, transparency is supported only for the following properties: **AppWindowTitleBar.ButtonBackgroundColor**, **AppWindowTitleBar.ButtonInactiveBackgroundColor**, **AppWindowTitleBar.ButtonPressedBackgroundColor**, **AppWindowTitleBar.ButtonHoverBackgroundColor** and **AppWindowTitleBar.BackgroundColor** (implicitly set).

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
Properties of ApplicationViewTitleBar	Properties of AppWindowTitleBar	Properties of AppWindowTitleBar
BackgroundColor	BackgroundColor	BackgroundColor
ButtonBackgroundColor	ButtonBackgroundColor	ButtonBackgroundColor
ButtonForegroundColor	ButtonForegroundColor	ButtonForegroundColor
ButtonHoverBackgroundColor	ButtonHoverBackgroundColor	ButtonHoverBackgroundColor
ButtonHoverForegroundColor	ButtonHoverForegroundColor	ButtonHoverForegroundColor
ButtonInactiveBackgroundColor	ButtonInactiveBackgroundColor	ButtonInactiveBackgroundColor
ButtonInactiveForegroundColor	ButtonInactiveForegroundColor	ButtonInactiveForegroundColor
ButtonPressedBackgroundColor	ButtonPressedBackgroundColor	ButtonPressedBackgroundColor
ButtonPressedForegroundColor	ButtonPressedForegroundColor	ButtonPressedForegroundColor
ForegroundColor	ForegroundColor	ForegroundColor
InactiveBackgroundColor	InactiveBackgroundColor	InactiveBackgroundColor
InactiveForegroundColor	InactiveForegroundColor	InactiveForegroundColor

These Windows App SDK APIs are for further customization of the system-drawn title bar in addition to the AppWindow.Title API.

- AppWindow.SetIcon. Sets the title bar and taskbar icon picture using either an hIcon handle or a string path to a resource or to a file.
- AppWindowTitleBar.IconShowOptions. Gets or sets a value that specifies how the window icon is displayed in the title bar. Supports two values currently—**HideIconAndSystemMenu** and **ShowIconAndSystemMenu**.
- AppWindowTitleBar.ResetToDefault. Resets the current title bar back to the default settings for the window.

App-drawn custom title bar (full customization)

If you're migrating to using **AppWindowTitleBar**, then we recommend that you check AppWindowTitleBar.IsCustomizationSupported in your code before calling the following custom title bar APIs.

Expand table

UWP ApplicationView/CoreWindow	Windows App SDK AppWindow
CoreApplicationViewTitleBar.ExtendViewIntoTitleBar	AppWindowTitleBar.ExtendsContentIntoTitleBar The platform continues to draw the **Minimize**/**Maximize**/**Close** buttons for you, and reports the occlusion information.
CoreApplicationViewTitleBar.SystemOverlayLeftInset	AppWindowTitleBar.LeftInset
CoreApplicationViewTitleBar.SystemOverlayRightInset	AppWindowTitleBar.RightInset
CoreApplicationViewTitleBar.Height	AppWindowTitleBar.Height
AppWindowTitleBarOcclusion AppWindowTitleBar.GetTitleBarOcclusions	Represents the system-reserved regions of the app window that will occlude app content if **ExtendsContentIntoTitleBar** is true. The Windows App SDK **AppWindow** left and right inset information, coupled with title bar height, provide the same information. AppWindowTitleBar.LeftInset, AppWindowTitleBar.RightInset, AppWindowTitleBar.Height

These Windows App SDK APIs are for full title bar customization.

- AppWindowTitleBar.SetDragRectangles. Sets the drag regions for the window.
- AppWindowTitleBar.ResetToDefault. Resets the current title bar back to the default settings for the window.

These UWP **AppWindow** APIs have no direct 1:1 mapping to a Windows App SDK API.

- AppWindowTitleBarVisibility. Defines constants that specify the preferred visibility of an **AppWindowTitleBar**.
- AppWindowTitleBar.GetPreferredVisibility. Retrieves the preferred visibility mode for the title bar.
- AppWindowTitleBar.SetPreferredVisibility. Sets the preferred visibility mode for the title bar.

For more details on how to work with **AppWindowTitleBar**, see the Windowing gallery sample. It demonstrates how to create a custom color title bar and how to draw a custom title bar.

Event handling

If your UWP app uses the AppWindow.Changed event, then you can migrate that code to the Microsoft.UI.Windowing.AppWindow.Changed event.

Size changed event

When migrating size changed event-handling code, you should switch to using the Windows App SDK AppWindowChangedEventArgs.DidSizeChange property. The value is `true` if the size of the app window changed, otherwise it's `false`.

Expand table

UWP ApplicationView/CoreWindow	UWP AppWindow	Windows App SDK
CoreWindow.SizeChanged	AppWindowChangedEventArgs.DidSizeChange	AppWindowChangedEventArgs.DidSizeChange

MainPage and MainWindow

When you create a new UWP project in Visual Studio, the project template provides you with a **MainPage** class. For your app, you might have renamed that class (and/or added more pages and user controls). The project template also provides you with navigation code in the methods of the **App** class.

When you create a new Windows App SDK project in Visual Studio, the project template provides you with a **MainWindow** class (of type Microsoft.UI.Xaml.Window), but no **Page**. And the project template doesn't provide any navigation code.

However, you have the option to add pages and user controls to your Windows App SDK project. For example, you could add a new page item to the project (**WinUI** > **Blank Page (WinUI 3)**), and name it `MainPage.xaml`, or some other name. That would add to your project a new class of type Microsoft.UI.Xaml.Controls.Page. Then, for info about adding navigation code to the project, see Do I need to implement page navigation?.

For Windows App SDK apps that are simple enough, you needn't create pages or user controls, and you can copy your XAML markup and code-behind into **MainWindow**. But for info about exceptions to that workflow, see Visual State Manager, and Page.Resources.

Change CoreWindow.Dispatcher to Window.DispatcherQueue

Some use cases for UWP's **Windows.UI.Core.CoreWindow** class migrate to the Windows App SDK's **Microsoft.UI.Xaml.Window**.

For example, if you're using the **Windows.UI.Core.CoreWindow.Dispatcher** property in your UWP app, then the solution is *not* to migrate to the **Microsoft.UI.Xaml.Window.Dispatcher** property (which always returns null). Instead, migrate to the **Microsoft.UI.Xaml.Window.DispatcherQueue** property, which returns a **Microsoft.UI.Dispatching.DispatcherQueue**.

For more info, and code examples, see Change Windows.UI.Core.CoreDispatcher to Microsoft.UI.Dispatching.DispatcherQueue.

Application lifecycle functionality migration

Article • 09/06/2023

This topic contains migration guidance in the application lifecycle area.

Important APIs

- **AppInstance** class
- **Application.OnLaunched** method
- **AppInstance.GetActivatedEventArgs** method
- **ExtendedActivationKind** enum

Summary of API and/or feature differences

Universal Windows Platform (UWP) apps are single-instanced by default; Windows App SDK (WinUI 3) apps are multi-instanced by default.

A UWP app has **App** methods such as **OnFileActivated**, **OnSearchActivated**, **OnActivated**, and **OnBackgroundActivated** that implicitly tell you how the app was activated; In a Windows App SDK app, in **App.OnLaunched** (or in any method), call (**AppInstance.GetActivatedEventArgs**) to retrieve the activated event args, and check them to determine how the app was activated.

Also see the *Background tasks* row in the table in the What's supported when migrating from UWP to WinUI 3 topic.

Single-instanced apps

Universal Windows Platform (UWP) apps are single-instanced by default (you can opt in to support multiple instances—see Create a multi-instance UWP app).

So the way a single-instanced UWP app behaves is that the second (and subsequent) time you launch, your current instance is activated. Let's say for example that in your UWP app you've implemented the file type association feature. If from File Explorer you open a file (of the type for which the app has registered a file type association)—and your app is already running—then that already-running instance is activated.

Windows App SDK (WinUI 3) apps, on the other hand, are multi-instanced by default. So, by default, the second (and subsequent) time you launch a Windows App SDK (WinUI 3) app, a new instance of the app is launched. If for example a Windows App SDK (WinUI 3) app implements file type association, and from File Explorer you open a file (of the right type) while that app is already running, then by default a new instance of the app is launched.

If you want your Windows App SDK (WinUI 3) app to be single-instanced like your UWP app is, then you can override the default behavior described above. You'll use **AppInstance.FindOrRegisterForKey** and **AppInstance.IsCurrent** to determine whether the current instance is the main instance. If it isn't, then you'll call **AppInstance.RedirectActivationToAsync** to redirect activation to the already-running main instance, and then exit from the current instance (without creating nor activating its main window).

For more info, see App instancing with the app lifecycle API.

> **Important**
>
> The code shown below works as expected provided that you target the *x64* architecture. That applies to both C# and C++/WinRT.

Single-instancing in Main or wWinMain

It's best to check for the need to redirect activation as early as possible in your app's execution. For that reason, we recommend that you perform your single-instancing logic in your app's **Main** (or **wWinMain** for C++/WinRT) function. This section shows you how.

Ordinarily, your app's **Main** function is auto-generated by the build system, and placed into a hidden file. So the first step is to configure your project not to auto-generate that function. To do that, you define the symbol *DISABLE_XAML_GENERATED_MAIN* in project **Properties**.

Instructions for C#

Go to **Properties** > (select **All Configurations** and **All Platforms**) > **Build** > **Conditional compilation symbols**, and paste in the symbol *DISABLE_XAML_GENERATED_MAIN*.

Because we've just prevented the project from auto-generating a **Main** function, the project won't build at the moment. So the second and last step is to implement our own

version of that function in a source code file.

Add a new project item of type **Class** to the project, and name it *Program.cs*. Inside `Program.cs`, replace the code `class Program {}` with your own implementation. For an example of the code to use, see `Program.cs` in the AppLifecycle sample.

Instructions for C++/WinRT

Go to **Properties** > (select **All Configurations** and **All Platforms**) > **Configuration Properties** > **C/C++** > **Preprocessor** > **Preprocessor Definitions**, **Edit** the value, and add the symbol *DISABLE_XAML_GENERATED_MAIN*.

Because we've just prevented the project from auto-generating a **wWinMain** function, the project won't build at the moment. So the second and last step is to implement our own version of that function in a source code file.

Add a reference to the Microsoft.Windows.ImplementationLibrary NuGet package, and update your project's `pch.h` and `App.xaml.cpp` source code files. For an example of the code to use, see the AppLifecycle sample. Be sure to change the namespace in `winrt::CppWinUiDesktopInstancing::implementation::App` to suit your particular project).

To resolve "error C2872: 'Microsoft': ambiguous symbol", change `using namespace Microsoft::UI::Xaml;` to `using namespace winrt::Microsoft::UI::Xaml;`. And make any additional similar changes to `using` directives.

Single-instancing in Application.OnLaunched

An alternative to using **Main** or **wWinMain** is to perform your single-instancing logic in the **Application.OnLaunched** method of your **App** class.

> **Important**
>
> Doing this work in **Application.OnLaunched** can simplify your app. However, a lot depends on what else your app is doing. If you're going to end up redirecting, and then terminating the current instance, then you'll want to avoid doing any throwaway work (or even work that needs explicitly undoing). In cases like that, **Application.OnLaunched** might be too late, and you might prefer to do the work in your app's **Main** or **wWinMain** function.

C#

```
// App.xaml.cs in a Windows App SDK (WinUI 3) app
...
protected override async void
OnLaunched(Microsoft.UI.Xaml.LaunchActivatedEventArgs args)
{
    // If this is the first instance launched, then register it as the
"main" instance.
    // If this isn't the first instance launched, then "main" will already
be registered,
    // so retrieve it.
    var mainInstance =
Microsoft.Windows.AppLifecycle.AppInstance.FindOrRegisterForKey("main");

    // If the instance that's executing the OnLaunched handler right now
    // isn't the "main" instance.
    if (!mainInstance.IsCurrent)
    {
        // Redirect the activation (and args) to the "main" instance, and
exit.
        var activatedEventArgs =

Microsoft.Windows.AppLifecycle.AppInstance.GetCurrent().GetActivatedEventArg
s();
        await mainInstance.RedirectActivationToAsync(activatedEventArgs);
        System.Diagnostics.Process.GetCurrentProcess().Kill();
        return;
    }

    m_window = new MainWindow();
    m_window.Activate();
}
```

Alternatively, you can call **AppInstance.GetInstances** to retrieve a collection of running **AppInstance** objects. If the number of elements in that collection is greater than 1, then your main instance is already running, and you should redirect to that.

File type association

In a Windows App SDK project, to specify the extension point for a file type association, you make the same settings in your `Package.appxmanifest` file as you would for a UWP project. Here are those settings.

Open `Package.appxmanifest`. In **Declarations**, choose **File Type Associations**, and click **Add**. Set the following properties.

Display name: MyFile **Name**: myfile **File type**: .myf

To register the file type association, build the app, launch it, and close it.

The difference comes in the imperative code. In a UWP app, you implement **App::OnFileActivated** in order to handle file activation. But in a Windows App SDK app, you write code in **App::OnLaunched** to check the extended activation kind (**ExtendedActivationKind**) of the activated event args (**AppInstance.GetActivatedEventArgs**), and see whether the activation is a file activation.

> ⓘ **Note**
>
> Don't use the Microsoft.UI.Xaml.LaunchActivatedEventArgs object passed to **App::OnLaunched** to determine the activation kind, because it reports "Launch" unconditionally.

If your app has navigation, then you'll already have navigation code in **App::OnLaunched**, and you might want to re-use that logic. For more info, see Do I need to implement page navigation?.

C#

```
// App.xaml.cs in a Windows App SDK app
...
using Microsoft.Windows.AppLifecycle;
...
protected override void
OnLaunched(Microsoft.UI.Xaml.LaunchActivatedEventArgs args)
{
    var activatedEventArgs =
Microsoft.Windows.AppLifecycle.AppInstance.GetCurrent().GetActivatedEventArg
s();
    if (activatedEventArgs.Kind ==
Microsoft.Windows.AppLifecycle.ExtendedActivationKind.File)
    {
        ...
    }
    ...
}
```

OnActivated, OnBackgroundActivated, and other activation-handling methods

In a UWP app, to override the various means by which your app can be activated, you can override corresponding methods on your **App** class, such as **OnFileActivated**, **OnSearchActivated**, or the more general **OnActivated**.

In a Windows App SDK app, in **App.OnLaunched** (or in fact at any time) you can call (**AppInstance.GetActivatedEventArgs**) to retrieve the activated event args, and check them to determine how the app was activated.

See the File type association section above for more details and a code example. You can apply the same technique for any activation kind specified by the **ExtendedActivationKind** enum.

App notifications from UWP to WinUI 3 migration

Article • 11/17/2022

The only difference when migrating app notification code from UWP to WinUI 3 is in handling the activation of notifications. Sending and managing app notifications remains exactly the same.

> **Note**
>
> The term "toast notification" is being replaced with "app notification". These terms both refer to the same feature of Windows, but over time we will phase out the use of "toast notification" in the documentation.

> **Note**
>
> **Some information relates to pre-released product, which may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.**

Activation differences

Windows App SDK

Expand table

Category	UWP	WinUI 3
Foreground activation entry point	`OnActivated` method inside `App.xaml.cs` is called	`OnLaunched` method inside `App.xaml.cs` is called.
Background activation entry point	Handled separately as a background task	Same as foreground activation. `OnLaunched` method inside `App.xaml.cs` is called. Use GetActivatedEventArgs to determine if the app should fully launch or just handle task and quit.
Window activation	Your window is automatically brought to	You must bring your window to the foreground if desired

Category	UWP	WinUI 3
	foreground when foreground activation occurs	

Migration for C# apps

Step 1: Install NuGet library

Windows App SDK

For a WinUI 3 app, you handle activation for notifications by using the AppNotificationManager class. This class is provided by the Microsoft.WindowsAppSDK Nuget package, which is included by default in the WinUI 3 Visual Studio project templates.

Step 2: Update your manifest

In your **Package.appxmanifest**, add:

1. Declaration for **xmlns:com**
2. Declaration for **xmlns:desktop**
3. In the **IgnorableNamespaces** attribute, **com** and **desktop**
4. **desktop:Extension** for **windows.toastNotificationActivation** to declare your toast activator CLSID (using a new GUID of your choice).
5. MSIX only: **com:Extension** for the COM activator using the GUID from step #4. Be sure to include the `Arguments="----AppNotificationActivated:"` so that you know your launch was from a notification

Windows App SDK

XML

```
<!--Add these namespaces-->
<Package
  ...
  xmlns:com="http://schemas.microsoft.com/appx/manifest/com/windows10"

xmlns:desktop="http://schemas.microsoft.com/appx/manifest/desktop/windows10"
```

```
  IgnorableNamespaces="... com desktop">
  ...
  <Applications>
    <Application>
      ...
      <Extensions>

        <!--Specify which CLSID to activate when app notification
clicked-->
        <desktop:Extension
Category="windows.toastNotificationActivation">
          <desktop:ToastNotificationActivation
ToastActivatorCLSID="replaced-with-your-guid-C173E6ADF0C3" />
        </desktop:Extension>

        <!--Register COM CLSID LocalServer32 registry key-->
        <com:Extension Category="windows.comServer">
          <com:ComServer>
            <com:ExeServer Executable="YourProject.exe" Arguments="----
AppNotificationActivated:" DisplayName="App notification activator">
              <com:Class Id="replaced-with-your-guid-C173E6ADF0C3"
DisplayName="App notification activator"/>
            </com:ExeServer>
          </com:ComServer>
        </com:Extension>

      </Extensions>
    </Application>
  </Applications>
 </Package>
```

Step 3: Handle activation

Windows App SDK

In your app's startup code (typically App.xaml.cs), update your code using the following steps:

1. In **OnLaunched**, get the default instance of the AppNotificationManager class.
2. Register for the AppNotificationManager.NotificationInvoked event.
3. Call Microsoft.Windows.AppNotifications.AppNotificationManager.Register to register your app to receive notification events. It is important that your call this method after registering the **NotificationInvoked** handler.
4. Refactor your window launch/activation code into a dedicated `LaunchAndBringToForegroundIfNeeded` helper method, so you can call it from multiple places.

5. Create a `HandleNotification` helper method, so that it can be called from multiple places.
6. Call AppInstance.GetActivatedEventArgs and check the AppActivationArguments.Kind property of the returned object for the value ExtendedActivationKind.AppNotification.
7. If the activation kind is not **AppNotification** call the **LaunchAndBringToForegroundIfNeeded** helper method.
8. If the activation kind is **AppNotification** cast the AppActivationArguments.Data property to an AppNotificationActivatedEventArgs and pass it to the `HandleNotification` helper method.
9. In your **ApplicationManager.NotificationInvoked** handler, call the `HandleNotification` helper method.
10. Within your `HandleNotification` helper method, be sure to dispatch to the App or Window dispatcher before executing any UI-related code like showing a window or updating UI
11. **Migrate** your old UWP `OnActivated` code that handled app notification activation to your new `HandleNotification` helper method.

Migrated App.xaml.cs

cs

```
protected override void
OnLaunched(Microsoft.UI.Xaml.LaunchActivatedEventArgs args)
{
    m_window = new MainWindow();

    // To ensure all Notification handling happens in this process
instance, register for
    // NotificationInvoked before calling Register(). Without this a new
process will
    // be launched to handle the notification.
    AppNotificationManager notificationManager =
AppNotificationManager.Default;
    notificationManager.NotificationInvoked +=
NotificationManager_NotificationInvoked;
    notificationManager.Register();

    var activatedArgs =
Microsoft.Windows.AppLifecycle.AppInstance.GetCurrent().GetActivatedEven
tArgs();
    var activationKind = activatedArgs.Kind;
    if (activationKind != ExtendedActivationKind.AppNotification)
    {
```

```
        LaunchAndBringToForegroundIfNeeded();
    } else
    {

HandleNotification((AppNotificationActivatedEventArgs)activatedArgs.Data
);
    }

}

private void LaunchAndBringToForegroundIfNeeded()
{
    if (m_window == null)
    {
        m_window = new MainWindow();
        m_window.Activate();

        // Additionally we show using our helper, since if activated via
a app notification, it doesn't
        // activate the window correctly
        WindowHelper.ShowWindow(m_window);
    }
    else
    {
        WindowHelper.ShowWindow(m_window);
    }
}

private void
NotificationManager_NotificationInvoked(AppNotificationManager sender,
AppNotificationActivatedEventArgs args)
{
    HandleNotification(args);
}

private void HandleNotification(AppNotificationActivatedEventArgs args)
{
  // Use the dispatcher from the window if present, otherwise the app
dispatcher
  var dispatcherQueue = m_window?.DispatcherQueue ??
DispatcherQueue.GetForCurrentThread();

  dispatcherQueue.TryEnqueue(async delegate
  {

      switch (args.Arguments["action"])
      {
          // Send a background message
          case "sendMessage":
              string message = args.UserInput["textBox"].ToString();
              // TODO: Send it

              // If the UI app isn't open
              if (m_window == null)
```

```
                {
                    // Close since we're done
                    Process.GetCurrentProcess().Kill();
                }

                break;

            // View a message
            case "viewMessage":

                // Launch/bring window to foreground
                LaunchAndBringToForegroundIfNeeded();

                // TODO: Open the message
                break;
        }
    });
}

private static class WindowHelper
{
    [DllImport("user32.dll")]
    private static extern bool ShowWindow(IntPtr hWnd, int nCmdShow);

    [DllImport("user32.dll")]
    [return: MarshalAs(UnmanagedType.Bool)]
    private static extern bool SetForegroundWindow(IntPtr hWnd);

    public static void ShowWindow(Window window)
    {
        // Bring the window to the foreground... first get the window
handle...
        var hwnd = WinRT.Interop.WindowNative.GetWindowHandle(window);

        // Restore window if minimized... requires DLL import above
        ShowWindow(hwnd, 0x00000009);

        // And call SetForegroundWindow... requires DLL import above
        SetForegroundWindow(hwnd);
    }
}
```

Building app notification content

Windows App SDK

With Windows App SDK, you can still create app notification content using raw xml, but you can also create app notification content using the new **AppNotificationsBuilder** API which replaces the **ToastContentBuilder** class

provided by the Windows Community Toolkit. Send the app notification by calling AppNotificationManager.Show. Mixing Windows Community Toolkit and App SDK APIs is not recommended.

C#

```
using Microsoft.Windows.AppNotifications;
using Microsoft.Windows.AppNotifications.Builder;

...

var builder = new AppNotificationBuilder()
    .AddText("Send a message.")
    .AddTextBox("textBox")
    .AddButton(new AppNotificationButton("Send")
        .AddArgument("action", "sendMessage"));

var notificationManager = AppNotificationManager.Default;
notificationManager.Show(builder.BuildNotification());
```

Push notifications functionality migration

Article • 06/27/2024

This topic contains migration guidance in the push notifications feature area.

> **Important**
>
> Only raw push notifications and app push notifications are currently supported. Badge push notifications and tile push notifications are not supported.

Summary of API and/or feature differences

Push notifications can be broken down into these four separate stages.

Expand table

Stage	UWP	Windows App SDK
Identity	Partner Center (MSA)	Azure App Registration (AAD)
Channel request	Asynchronous	Asynchronous Azure App Registration Id Retry logic built in (up to 5 retries)
Activation	In-process, PushTrigger*, COM activation*	In-process, COM activation, ShellExecute
Sending push notifications	Uses login.live.com endpoint to receive an access token	Uses the `https://login.microsoftonline.com/{tenantID}/oauth2/token` endpoint for token request

* Supported for Windows 10, version 2004 (10.0; Build 19041), and later.

Identity setup

In the Windows App SDK, the push notifications feature uses identity from Azure App Registration (AAD), which removes the requirement of having a Package Family Name

(PFN) from Partner Center in order to use push notifications.

- For a **UWP app**, you sign up and register the application in Windows Store Partner Center.
- For a **Windows App SDK app**, you create an Azure account, and create an Azure App Registration (AAD).

Channel requests

Channel request are handled asynchronously, and require the Azure AppID GUID and Azure tenantID (you receive the Azure AppID and tenant ID from an AAD app registration). You use the Azure AppID for your identity in place of the Package Family Name (PFN) that a UWP app uses. In case the request runs into a retryable error, the notification platform will attempt multiple retries.

A Windows App SDK app can check the status of a channel request.

Activation

See the Windows App SDK registration and activation steps at Configure your app to receive push notifications.

Sending push notifications

A Windows App SDK app must request the access token from the AAD endpoint, rather than from the MSA endpoint.

Access Token Request

For **a UWP app**:

```HTTP
POST /accesstoken.srf HTTP/1.1
Host: login.live.com
Content-Type: application/x-www-form-urlencoded
Cookie: MSCC=73.140.231.96-US
Content-Length: 112

grant_type=client_credentials&client_id=<AppID_Here>&client_secret=
<Client_Secret_Here>&scope=notify.windows.com
```

For a **Windows App SDK app** (AAD access token request):

HTTP

```
POST /{tenantID}/oauth2/v2.0/token Http/1.1
Host: login.microsoftonline.com
Content-Type: application/x-www-form-urlencoded
Content-Length: 160

grant_type=client_credentials&client_id=
<Azure_App_Registration_AppId_Here>&client_secret=
<Azure_App_Registration_Secret_Here>&resource=https://wns.windows.com/
```

HTTP Post to WNS

When it comes to sending a HTTP POST request to WNS, there are no changes from UWP. The access token is still passed in the authorization header.

HTTP

```
POST /?token=[ChannelURI] HTTP/1.1
Host: dm3p.notify.windows.com
Content-Type: application/octet-stream
X-WNS-Type: wns/raw
Authorization: Bearer [your access token]
Content-Length: 46

{ Sync: "Hello from the Contoso App Service" }
```

DirectWrite to DWriteCore migration

Article • 06/24/2024

DWriteCore is the Windows App SDK implementation of DirectWrite. For more info, see DWriteCore overview.

Summary of API and/or feature differences

Nearly all DirectWrite APIs remain unchanged in DWriteCore. There are a few differences, as described in APIs that are new, or different, for DWriteCore.

As you'll see in that topic, DWriteCore has a more locked-down factory type, and has the ability to retrieve pixel data without using GDI.

Migration guidance

The only change necessary when moving from DirectWrite to DWriteCore is to include the `dwrite_core.h` header file. For more info, and code examples, see Programming with DWriteCore.

> ⚠ **Warning**
>
> DWriteCore does not currently support hardware-accelerated text rendering with Direct2D (D2D). It supports software text rendering only. This prevents apps that require D2D support from adopting DWriteCore at this time.

The DWriteCoreGallery sample app

MRT to MRT Core migration

Article • 03/22/2022

This topic contains guidance for migrating from UWP's Resource Management System (also known as MRT) to the Windows App SDK's MRT Core.

MRT Core is a streamlined version of MRT. For more info, see Manage resources with MRT Core.

Summary of API and/or feature differences

For ease of migration, MRT Core APIs are very similar to MRT APIs. For API reference documentation, see the Microsoft.Windows.ApplicationModel.Resources namespace.

> **Note**
>
> Not all of the MRT APIs exist in MRT Core. But all of the APIs necessary for the basic functionality of MRT are included.

Change namespace

In UWP, the MRT APIs are in the **Windows.ApplicationModel.Resources.Core** namespace. In the Windows App SDK, the MRT Core APIs are in the **Microsoft.Windows.ApplicationModel.Resources** namespace. So you'll need to change that namespace name in your source code (add `Microsoft.` at the start, and remove the `.Core` at the end).

> **Note**
>
> In Windows App SDK 1.0 Preview 1 and later releases, MRT Core APIs are in the Microsoft.Windows.ApplicationModel.Resources namespace. In releases earlier than that, they are in the **Microsoft.ApplicationModel.Resources** namespace.

ResourceManager class

This section applies if you're using the **Windows.ApplicationModel.Resources.Core.ResourceManager.Current** property in your UWP app.

C#

```
// In a UWP app
using Windows.ApplicationModel.Resources.Core;
...
var currentResourceManager = ResourceManager.Current;
```

C++/WinRT

```
// In a UWP app
#include <winrt/Windows.ApplicationModel.Resources.Core.h>
using namespace winrt::Windows::ApplicationModel::Resources::Core;
...
auto currentResourceManager{ ResourceManager::Current() };
```

Instead, in your Windows App SDK app, create a new Microsoft.Windows.ApplicationModel.Resources.ResourceManager.

C#

```
// In a Windows App SDK app
using Microsoft.Windows.ApplicationModel.Resources;
...
var currentResourceManager = new ResourceManager();
```

C++/WinRT

```
// In a Windows App SDK app
#include <winrt/Microsoft.Windows.ApplicationModel.Resources.h>
using namespace winrt::Microsoft::Windows::ApplicationModel::Resources;
...
ResourceManager currentResourceManager;
```

ResourceContext.GetForCurrentView, and ResourceContext.GetForViewIndependentUse

UWP's MRT ResourceContext class distinguishes between a **ResourceContext** for the current view, and one for view-independent use.

For the Windows App SDK's MRT Core ResourceContext class, your app needs to determine the correct context (resource qualifier values), and the concepts of current view and view-independent use no longer apply.

- So if you're using the **ResourceContext.GetForCurrentView** API or the **ResourceContext.GetForViewIndependentUse** API, then use ResourceManager.CreateResourceContext instead.

Resource qualifier values

In UWP's MRT, the resource context qualifier values are determined for the app. While in MRT Core, only the language value is populated. Your app needs to determine other values for itself. Here's an example, where it's assumed your XAML view contains an element named *layoutRoot*.

C#

```
// In a Windows App SDK app
using Microsoft.Windows.ApplicationModel.Resources;
...
var currentResourceManager = new ResourceManager();
var resourceContext = currentResourceManager.CreateResourceContext();
int scaleFactor = Convert.ToInt32(layoutRoot.XamlRoot.RasterizationScale *
100);
resourceContext.QualifierValues[KnownResourceQualifierName.Scale] =
scaleFactor.ToString();
string s =
resourceContext.QualifierValues[KnownResourceQualifierName.Scale];
```

C++/WinRT

```
// In a Windows App SDK app
#include <winrt/Microsoft.Windows.ApplicationModel.Resources.h>
using namespace winrt::Microsoft::Windows::ApplicationModel::Resources;
...
ResourceManager currentResourceManager;
auto resourceContext{ currentResourceManager.CreateResourceContext() };
auto scaleFactor{ layoutRoot().XamlRoot().RasterizationScale() * 100 };
resourceContext.QualifierValues().Insert(L"Scale",
std::to_wstring((int)scaleFactor));
auto s{ resourceContext.QualifierValues().Lookup(L"Scale") };
```

Resource qualifier value change

UWP's MRT provides the ResourceQualifierObservableMap.MapChanged event. And this section applies if your UWP app is handling that event in order to listen to qualifier value changes.

MRT Core doesn't provide any notification mechanics around environment changes. So your Windows App SDK app needs to detect such changes on its own if you wish to update resources based on environment changes.

An MRT Core sample app

Also see the Load resources using MRT Core sample app project, which demonstrates how to use the MRT Core API surface.

Background task migration strategy

Article • 03/19/2025

Background tasks are used heavily in UWP apps for performing jobs when a particular trigger is invoked on the machine. As these don't require any service to be running listening for the triggers, it's very power efficient. So, while migrating UWP apps to WinUI 3 and other desktop apps that use Windows App SDK, developers may require support for implementing background tasks on the platform.

Background tasks offered in the UWP app model can either be out-of-proc or in-proc. This article describes the migration strategy for each of these types when moving to BackgroundTaskBuilder APIs in Windows App SDK.

Out-of-proc background tasks

In the case of out-of-proc background tasks in UWP, background tasks will be written as a Windows Runtime (WinRT) component, and the component is set as the TaskEntryPoint on BackgroundTaskBuilder during registration. While migrating to Windows App SDK, developers can keep this as-is and package the WinRT component together with the desktop project. In this case, the broker infrastructure will be launching `backgroundtaskhost` process when the trigger is invoked, and the WinRT component background task would be executed in the process. In this approach, the background task would be running in a Low Integrity Level (IL) process (`backgroundtaskhost.exe`) while the main desktop project would be running in a Medium IL process.

If the application needs to to run a background task in a medium IL process itself, the full trust COM component needs to be used for background tasks. In that scenario, developers must use the Windows App SDK BackgroundTaskBuilder to register the full trust COM component. Note that the BackgroundTaskBuilder API from the **Windows.ApplicationModel.Background** namespace will throw exceptions while registering of some of the triggers.

A full WinUI 3 background task registration sample can be found on GitHub.

More details on the implementation are available here. The only required change would be to replace the WinRT BackgroundTaskBuilder API with the Windows App SDK API Microsoft.Windows.ApplicationModel.Background.BackgroundTaskBuilder.

In-proc background tasks

For in-proc background tasks in UWP, background task routines are implemented in the OnBackgroundActivated callback which runs as part of the foreground process. This won't be possible in a WinUI 3 application as the **OnBackgroundActivated** callbacks aren't available. The application needs to move the background task implementations to full trust COM tasks as described above and define the COM server in the package manifest to handle the COM activation of the task. When the trigger occurs, COM activation will happen on the corresponding COM Coclass registered for the trigger.

A full WinUI 3 background task registration sample can be found on GitHub.

More details on the implementation are available here. The only change would be to replace the WinRT BackgroundTaskBuilder API with the Windows App SDK APIs in Microsoft.Windows.ApplicationModel.Background.BackgroundTaskBuilder.

Windows App SDK BackgroundTaskBuilder API

This Windows App SDK **BackgroundTaskBuilder** API is created to support the full trust COM background task implementations in WinUI 3 and other desktop applications that use Windows App SDK, as the WinRT API throws exceptions during registration except for a few triggers.

The following code shows how to register background task using Windows App SDK BackgroundTaskBuilder APIs:

C++

```
//Using Windows App SDK API for BackgroundTaskBuilder
winrt::Microsoft::Windows::ApplicationModel::Background::BackgroundTaskBuild
er builder;
SystemTrigger trigger = SystemTrigger(SystemTriggerType::TimeZoneChange,
false);
auto backgroundTrigger = trigger.as<IBackgroundTrigger>();
builder.SetTrigger(backgroundTrigger);
builder.AddCondition(SystemCondition(SystemConditionType::InternetAvailable)
);
builder.SetTaskEntryPointClsid(classGuid);
builder.Register();
```

The following is the equivalent C# code:

C#

```
// Using Windows App SDK API for BackgroundTaskBuilder
var builder = new
Microsoft.Windows.ApplicationModel.Background.BackgroundTaskBuilder();
var trigger = new SystemTrigger(SystemTriggerType.TimeZoneChange, false);
```

```
builder.SetTrigger(trigger);
builder.AddCondition(new
SystemCondition(SystemConditionType.InternetAvailable));
builder.SetTaskEntryPointClsid(classGuid);
builder.Register();
```

To use this API, add the tag below to the project file to enable Windows App SDK background tasks:

XML

```
<WindowsAppSDKBackgroundTask>true</WindowsAppSDKBackgroundTask>
```

Also, in the manifest file, the **EntryPoint** for **BackgroundTask** is set to `Microsoft.Windows.ApplicationModel.Background.UniversalBGTask.Task`:

XML

```
<Extension Category="windows.backgroundTasks"
EntryPoint="Microsoft.Windows.ApplicationModel.Background.UniversalBGTask.Ta
sk">
    <BackgroundTasks>
        <Task Type="general"/>
    </BackgroundTasks>
</Extension>
```

For C# applications, an **ActivatableClass** registration should also be added to the manifest file:

XML

```
<Extension Category="windows.activatableClass.inProcessServer">
    <InProcessServer>

<Path>Microsoft.Windows.ApplicationModel.Background.UniversalBGTask.dll</Pat
h>
        <ActivatableClass
ActivatableClassId="Microsoft.Windows.ApplicationModel.Background.UniversalB
GTask.Task" ThreadingModel="both"/>
    </InProcessServer>
</Extension>
```

Leveraging TaskScheduler for background task migration

Task Scheduler helps desktop apps achieve the same functionality that is provided by BackgroundTaskBuilder in UWP apps. More details on implementations using **TaskScheduler** are available here.

ApplicationTrigger use in Windows App SDK applications

ApplicationTrigger is supported in UWP applications due to the lifetime management scenario where the application process can be suspended. This scenario does not occur for WinUI and other Windows App SDK desktop applications, so this trigger is not supported in WinUI applications. All logic related to **ApplicationTrigger** will need to be rewritten to execute by launching another process or by running in a thread pool thread. For more information, see CreateThread and CreateProcess.

Threading functionality migration

Article • 03/29/2023

This topic describes how to migrate the threading code in a Universal Windows Platform (UWP) application to the Windows App SDK.

Summary of API and/or feature differences

UWP's threading model is a variation of the single-threaded apartment (STA) model called Application STA (ASTA), which blocks reentrancy and helps avoid various reentrancy bugs and deadlocks. An ASTA thread is also known as a UI thread.

The Windows App SDK uses a standard STA threading model, which doesn't provide the same reentrancy safeguards.

The **CoreDispatcher** type migrates to **DispatcherQueue**. And the **CoreDispatcher.RunAsync** method migrates to **DispatcherQueue.TryEnqueue**.

C++/WinRT. If you're using **winrt::resume_foreground** with **CoreDispatcher**, then migrate that to use **DispatcherQueue** instead.

ASTA to STA threading model

For more detail on the ASTA threading model, see the blog post What is so special about the Application STA?.

As the Windows App SDK's STA threading model doesn't have the same assurances around preventing reentrancy issues, if your UWP app assumes the non re-entrant behavior of the ASTA threading model, then your code might not behave as expected.

One thing to watch out for is reentrancy into XAML controls (see the example in A Windows App SDK migration of the UWP Photo Editor sample app (C++/WinRT)). And for some crashes, such as access violations, the direct crash callstack is usually the right stack to use. But if it's a *stowed exception* crash—which has exception code: 0xc000027b—then more work is required to get the right callstack.

Stowed exceptions

Stowed exception crashes save away a possible error, and that gets used later if no part of the code handles the exception. XAML sometimes decides the error is fatal immediately, in which case the direct crash stack might be good. But more frequently

the stack has unwound before it was determined to be fatal. For more details about stowed exceptions, see the Inside Show episode Stowed Exception C000027B.

For stowed exception crashes (to see a nested message pump, or to see the XAML control's specific exception being thrown), you can get more info on the crash by loading a crash dump in the Windows Debugger (WinDbg) (see Download debugging tools for Windows), and then using `!pde.dse` to dump the stowed exceptions.

The PDE debugger extension (for the `!pde.dse` command) is available by downloading the PDE*.zip file from OneDrive. Put the appropriate x64 or x86 `.dll` from that zip file into the `winext` directory of your WinDbg install, and then `!pde.dse` will work on stowed exception crash dumps.

Frequently there'll be multiple stowed exceptions, with some at the end that were handled/ignored. Most commonly, the first stowed exception is the interesting one. In some cases, the first stowed exception might be a re-throw of the second, so if the second stowed exception shows deeper into the same stack as the first, then the second exception might be the origination of the error. The error code shown with each stowed exception is also valuable, since that provides the **HRESULT** associated with that exception.

Change Windows.UI.Core.CoreDispatcher to Microsoft.UI.Dispatching.DispatcherQueue

This section applies if you're using the **Windows.UI.Core.CoreDispatcher** class in your UWP app. That includes the use of any methods or properties that take or return a **CoreDispatcher**, such as the **DependencyObject.Dispatcher** and **CoreWindow.Dispatcher** properties. For example, you'll be calling **DependencyObject.Dispatcher** when you retrieve the **CoreDispatcher** belonging to a **Windows.UI.Xaml.Controls.Page**.

C#

```
// MainPage.xaml.cs in a UWP app
if (this.Dispatcher.HasThreadAccess)
{
    ...
}
```

Instead, in your Windows App SDK app, you'll need to use the **Microsoft.UI.Dispatching.DispatcherQueue** class. And the corresponding methods or properties that take or return a **DispatcherQueue**, such as the

DependencyObject.DispatcherQueue and Microsoft.UI.Xaml.Window.DispatcherQueue properties. For example, you'll be calling **DependencyObject.DispatcherQueue** when you retrieve the **DispatcherQueue** belonging to a Microsoft.UI.Xaml.Controls.Page (most XAML objects are **DependencyObject**s).

C#

```
// MainPage.xaml.cs in a Windows App SDK app
if (this.DispatcherQueue.HasThreadAccess)
{
    ...
}
```

Change CoreDispatcher.RunAsync to DispatcherQueue.TryEnqueue

This section applies if you're using the Windows.UI.Core.CoreDispatcher.RunAsync method to schedule a task to run on the main UI thread (or on the thread associated with a particular Windows.UI.Core.CoreDispatcher).

C#

```
// MainPage.xaml.cs in a UWP app
public void NotifyUser(string strMessage)
{
    if (this.Dispatcher.HasThreadAccess)
    {
        StatusBlock.Text = strMessage;
    }
    else
    {
        var task = this.Dispatcher.RunAsync(
            Windows.UI.Core.CoreDispatcherPriority.Normal,
            () => StatusBlock.Text = strMessage);
    }
}
```

In your Windows App SDK app, use the Microsoft.UI.Dispatching.DispatcherQueue.TryEnqueue) method instead. It adds to the Microsoft.UI.Dispatching.DispatcherQueue a task that will be executed on the thread associated with the **DispatcherQueue**.

C#

```
// MainPage.xaml.cs in a Windows App SDK app
public void NotifyUser(string strMessage)
{
    if (this.DispatcherQueue.HasThreadAccess)
    {
        StatusBlock.Text = strMessage;
    }
    else
    {
        bool isQueued = this.DispatcherQueue.TryEnqueue(
        Microsoft.UI.Dispatching.DispatcherQueuePriority.Normal,
        () => StatusBlock.Text = strMessage);
    }
}
```

Migrate winrt::resume_foreground (C++/WinRT)

This section applies if you use the **winrt::resume_foreground** function in a coroutine in your C++/WinRT UWP app.

In UWP, the use case for **winrt::resume_foreground** is to switch execution to a foreground thread (that foreground thread is often the one that's associated with a **Windows.UI.Core.CoreDispatcher**). Here's an example of that.

```
// MainPage.cpp in a UWP app
winrt::fire_and_forget MainPage::ClickHandler(IInspectable const&,
RoutedEventArgs const&)
{
    ...
    co_await winrt::resume_foreground(this->Dispatcher());
    ...
}
```

In your Windows App SDK app:

- Instead of **winrt::resume_foreground**, you'll need to use **wil::resume_foreground** (from the Windows Implementation Libraries (WIL)).
- And instead of **CoreDispatcher**, you'll need to use the **Microsoft.UI.Dispatching.DispatcherQueue** class, as described in Change Windows.UI.Core.CoreDispatcher to Microsoft.UI.Dispatching.DispatcherQueue.

So first add a reference to the Microsoft.Windows.ImplementationLibrary NuGet package.

Then add the following include to `pch.h` in the target project.

C++/WinRT

```
#include <wil/cppwinrt_helpers.h>
```

And then follow the pattern shown below.

C++/WinRT

```
// MainPage.xaml.cpp in a Windows App SDK app
...
winrt::fire_and_forget MainPage::ClickHandler(IInspectable const&,
RoutedEventArgs const&)
{
    ...
    co_await wil::resume_foreground(this->DispatcherQueue());
    ...
}
```

A Windows App SDK migration of the UWP PhotoLab sample app (C#)

Article • 03/27/2023

This topic is a case study of taking the C# UWP PhotoLab sample app, and migrating it to the Windows App SDK.

Begin by cloning the UWP sample app's repo, and opening the solution in Visual Studio.

> **Important**
>
> For considerations and strategies for approaching the migration process, and how to set up your development environment for migrating, see **Overall migration strategy**. It's particularly important to see **What's supported when porting from UWP to WinUI 3** so that you can ensure that all the features you need for your app are supported before you attempt migration.

Install tools for the Windows App SDK

To set up your development computer, see Install tools for the Windows App SDK.

> **Important**
>
> You'll find release notes topics along with the **Windows App SDK release channels** topic. There are release notes for each channel. Be sure to check any *limitations and known issues* in those release notes, since those might affect the results of following along with this case study and/or running the migrated app.

Create a new project

In Visual Studio, create a new C# project from the **Blank App, Packaged (WinUI 3 in Desktop)** project template. Name the project *PhotoLabWinUI*, uncheck **Place solution and project in the same directory**. You can target the most recent release (not preview) of the client operating system.

> **Note**

We'll be referring to the UWP version of the sample project (the one that you cloned from its **repo**) as the *source* solution/project. We'll be referring to the Windows App SDK version as the *target* solution/project.

The order in which we'll migrate the code

MainPage is an important and prominent piece of the app. But if we were to begin by migrating that, then we'd soon realize that **MainPage** has a dependency on the **DetailPage** view; and then that **DetailPage** has a dependency on the **ImageFileInfo** model. So for this walkthrough we'll take this approach.

- We'll begin by copying over the asset files.
- Then we'll migrate the **ImageFileInfo** model.
- Next we'll migrate the **App** class (since that needs changes making to it that **DetailPage**, **MainPage**, and **LoadedImageBrush** will depend on).
- Then we'll migrate the **LoadedImageBrush** class.
- Then we'll begin migrating the views, starting with **DetailPage** first.
- And we'll finish up by migrating the **MainPage** view.

Copy asset files

1. In your target project in Visual Studio, in **Solution Explorer**, right-click the **Assets** folder, and add a new folder named `Samples`.

2. In your clone of the source project, in **File Explorer**, locate the folder **Windows-appsample-photo-lab** > **PhotoLab** > **Assets**. You'll find seven asset files in that folder, together with a subfolder named **Samples** containing sample images. Select those seven asset files, and the **Samples** subfolder, and copy them to the clipboard.

3. Also in **File Explorer**, now locate the corresponding folder in the target project that you created. The path to that folder is **PhotoLabWinUI** > **PhotoLabWinUI** > **Assets**. Paste into that folder the asset files and the subfolder that you just copied, and accept the prompt to replace any files that already exist in the destination.

4. In your target project in Visual Studio, in **Solution Explorer**, with the **Assets** folder expanded, you'll see in the **Samples** folder the contents of the **Samples** subfolder (which you just pasted). You can hover the mouse pointer over the asset files. A thumbnail preview will appear for each, confirming that you've replaced/added the asset files correctly.

Migrate the ImageFileInfo model

ImageFileInfo is a *model* (in the sense of models, views, and viewmodels) that represents an image file, such as a photo.

Copy ImageFileInfo source code files

1. In your clone of the source project, in **File Explorer**, locate the folder **Windows-appsample-photo-lab** > **PhotoLab**. In that folder you'll find the source code file `ImageFileInfo.cs`; that file contains the implementation of **ImageFileInfo**. Select that file, and copy it to the clipboard.

2. In Visual Studio, right-click the target project node, and click **Open Folder in File Explorer**. This opens the target project folder in **File Explorer**. Paste into that folder the file that you just copied.

Migrate ImageFileInfo source code

1. Make the following find/replacements (match case and whole word) in the `ImageFileInfo.cs` file that you just pasted.

- `namespace PhotoLab` => `namespace PhotoLabWinUI`
- `Windows.UI.Xaml` => `Microsoft.UI.Xaml`

Windows.UI.Xaml is the namespace for UWP XAML; **Microsoft.UI.Xaml** is the namespace for WinUI XAML.

> ⓘ **Note**
>
> The Mapping UWP APIs to the Windows App SDK topic provides a mapping of UWP APIs to their Windows App SDK equivalents. The change we made above is an example of a namespace name change necessary during the migration process.

2. Now confirm that you can build the target solution (but don't run yet).

Migrate the App class

1. From the source project, in the `<Application.Resources>` element in `App.xaml`, find the following four lines. Copy them, and paste them into the target project.

```
XAML
```

```
<SolidColorBrush x:Key="RatingControlSelectedForeground" Color="White"/>
<!--  Window width adaptive breakpoints.  -->
<x:Double x:Key="MinWindowBreakpoint">0</x:Double>
<x:Double x:Key="MediumWindowBreakpoint">641</x:Double>
<x:Double x:Key="LargeWindowBreakpoint">1008</x:Double>
```

> **Note**
>
> Because the target project will use different (and simpler) navigation from the source project, there's no need to copy over any further code from the source project's `App.xaml.cs`.

2. In the target project, **App** stores the main window object in its private field *m_window*. Later in the migration process (when we migrate the source project's use of **Window.Current**), it'll be convenient if that private field is instead a public static property. So replace the *m_window* field with a *Window* property, and change references to *m_window*, as shown below.

C#

```
// App.xaml.cs
public partial class App : Application
{
    ...
    protected override void
OnLaunched(Microsoft.UI.Xaml.LaunchActivatedEventArgs args)
    {
        Window = new MainWindow();
        Window.Activate();
    }

    public static MainWindow Window { get; private set; }
}
```

3. Later in the migration process (when we migrate the code that displays a FileSavePicker), it'll be convenient if **App** exposes the main window's *handle* (**HWND**). So add a *WindowHandle* property, and initialize it in the **OnLaunched** method, as shown below.

C#

```
// App.xaml.cs
public partial class App : Application
{
    ...
```

```
    protected override void
OnLaunched(Microsoft.UI.Xaml.LaunchActivatedEventArgs args)
    {
        Window = new MainWindow();
        Window.Activate();
        WindowHandle = WinRT.Interop.WindowNative.GetWindowHandle(Window);
    }

    public static IntPtr WindowHandle { get; private set; }
}
```

Migrate the LoadedImageBrush model

LoadedImageBrush is a specialization of **XamlCompositionBrushBase**. The *PhotoLab* sample app uses the **LoadedImageBrush** class to apply effects to photos.

Reference the Win2D NuGet package

To support code in **LoadedImageBrush**, the source project has a dependency on Win2D. So we'll also need a dependency on Win2D in our target project.

In the target solution in Visual Studio, click **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution...** > **Browse**, and type or paste *Microsoft.Graphics.Win2D*. Select the correct item in search results, check the *PhotoLabWinUI* project, and click **Install** to install the package into that project.

Copy LoadedImageBrush source code files

Copy `LoadedImageBrush.cs` from the source project to the target project in the same way that you copied `ImageFileInfo.cs`.

Migrate LoadedImageBrush source code

1. Make the following find/replacements (match case and whole word) in the `LoadedImageBrush.cs` file that you just pasted.

- `namespace PhotoLab` => `namespace PhotoLabWinUI`
- `Windows.UI.Composition` => `Microsoft.UI.Composition`
- `Windows.UI.Xaml` => `Microsoft.UI.Xaml`
- `Window.Current.Compositor` => `App.Window.Compositor` (see Change Windows.UI.Xaml.Window.Current to App.Window)

2. Confirm that you can build the target solution (but don't run yet).

Migrate the DetailPage view

DetailPage is the class that represents the photo editor page, where Win2D effects are toggled, set, and chained together. You get to the photo editor page by selecting a photo thumbnail on **MainPage**. **DetailPage** is a *model* (in the sense of models, views, and viewmodels).

Copy DetailPage source code files

Copy `DetailPage.xaml` and `DetailPage.xaml.cs` from the source project to the target project in the same way that you copied files in previous steps.

Migrate DetailPage source code

1. Make the following find/replacements (match case and whole word) in the `DetailPage.xaml` file that you just pasted.

- `PhotoLab` => `PhotoLabWinUI`

2. Make the following find/replacements (match case and whole word) in the `DetailPage.xaml.cs` file that you just pasted.

- `namespace PhotoLab` => `namespace PhotoLabWinUI`
- `Windows.UI.Colors` => `Microsoft.UI.Colors`
- `Windows.UI.Xaml` => `Microsoft.UI.Xaml`

3. For the next step, we'll make the change that's explained in ContentDialog, and Popup. So, still in `DetailPage.xaml.cs`, in the **ShowSaveDialog** method, immediately *before* the line `ContentDialogResult result = await saveDialog.ShowAsync();`, add this code.

C++/WinRT

```
if
(Windows.Foundation.Metadata.ApiInformation.IsApiContractPresent("Windows.Fo
undation.UniversalApiContract", 8))
{
    saveDialog.XamlRoot = this.Content.XamlRoot;
}
```

4. Still in `DetailPage.xaml.cs`, in the **OnNavigatedTo** method, delete the following two lines of code. Just those two lines; later in this case study, we'll reintroduce the back button functionality that we just removed.

```
C#

...
SystemNavigationManager.GetForCurrentView().AppViewBackButtonVisibility =
    AppViewBackButtonVisibility.Visible;
...
SystemNavigationManager.GetForCurrentView().AppViewBackButtonVisibility =
    AppViewBackButtonVisibility.Collapsed;
...
```

5. For this step, we'll make the change that's explained in MessageDialog, and Pickers. Still in `DetailPage.xaml.cs`, in the **ExportImage** method, immediately *before* the line `var outputFile = await fileSavePicker.PickSaveFileAsync();`, add this line of code.

```
C#

WinRT.Interop.InitializeWithWindow.Initialize(fileSavePicker,
App.WindowHandle);
```

MainPage has dependencies on **DetailPage**, which is why we migrated **DetailPage** first. But **DetailPage** has dependencies on **MainPage**, too, so we won't be able to build yet.

Migrate the MainPage view

The main page of the app represents the view that you see first when you run the app. It's the page that loads the photos from the **Samples** folder that's built into the sample app, and displays a tiled thumbnail view.

Copy MainPage source code files

Copy `MainPage.xaml` and `MainPage.xaml.cs` from the source project to the target project in the same way that you copied files in previous steps.

Migrate MainPage source code

1. Make the following find/replacements (match case and whole word) in the `MainPage.xaml` file that you just pasted.

- `PhotoLab` => `PhotoLabWinUI`

2. Still in `MainPage.xaml`, find the markup `animations:ReorderGridAnimation.Duration="400"`, and delete that.

3. Make the following find/replacements (match case and whole word) in the `MainPage.xaml.cs` file that you just pasted.

- `namespace PhotoLab` => `namespace PhotoLabWinUI`
- `Windows.UI.Xaml` => `Microsoft.UI.Xaml`

4. For this step, we'll make the change that's explained in ContentDialog, and Popup. So, still in `MainPage.xaml.cs`, in the **GetItemsAsync** method, immediately *before* the line `ContentDialogResult resultNotUsed = await unsupportedFilesDialog.ShowAsync();`, add this code.

C++/WinRT

```
if
(Windows.Foundation.Metadata.ApiInformation.IsApiContractPresent("Windows.Fo
undation.UniversalApiContract", 8))
{
    unsupportedFilesDialog.XamlRoot = this.Content.XamlRoot;
}
```

5. Still in `MainPage.xaml.cs`, in the **OnNavigatedTo** method, delete the following line of code.

C#

```
SystemNavigationManager.GetForCurrentView().AppViewBackButtonVisibility =
    AppViewBackButtonVisibility.Collapsed;
```

Later in this case study, we'll reintroduce the back button functionality that we just removed.

6. Confirm that you can build the target solution (but don't run yet).

Navigate to MainPage

The *PhotoLab* sample app uses navigation logic to navigate initially to **MainPage** (and then between **MainPage** and **DetailPage**). For more info about Windows App SDK apps that need navigation (and those that don't), see Do I need to implement page navigation?.

So the changes we'll make next support that navigation.

1. In `MainWindow.xaml`, delete the `<StackPanel>` element, and replace it with just a named `<Frame>` element. The result looks like this:

XAML

```
<Window ...>
    <Frame x:Name="rootFrame"/>
</Window>
```

2. In `MainWindow.xaml.cs`, delete the **myButton_Click** method.

3. Still in `MainWindow.xaml.cs`, add the following line of code to the constructor.

C#

```
public sealed partial class MainWindow : Window
{
    public MainWindow()
    {
        this.InitializeComponent();
        rootFrame.Navigate(typeof(MainPage));
    }
}
```

4. Confirm that you can build the target solution (but don't run yet).

Restoring back button functionality

1. In `DetailPage.xaml`, the root element is a **RelativePanel**. Add the following markup inside that **RelativePanel**, immediately after the **StackPanel** element.

XAML

```
<AppBarButton x:Name="BackButton" Click="BackButton_Click"
Margin="0,0,12,0">
    <SymbolIcon Symbol="Back"/>
</AppBarButton>
```

2. In `DetailPage.xaml.cs`, add the following two lines of code to the **OnNavigatedTo** method, in the place indicated.

C#

```
if (this.Frame.CanGoBack)
{
    BackButton.Visibility = Microsoft.UI.Xaml.Visibility.Visible;
}
else
{
    BackButton.Visibility = Microsoft.UI.Xaml.Visibility.Collapsed;
}
```

3. Still in `DetailPage.xaml.cs`, add the following event handler.

C#

```
private void BackButton_Click(object sender,
Microsoft.UI.Xaml.RoutedEventArgs e)
{
    Frame.GoBack();
}
```

Test the migrated app

Now build the project, and run the app to test it. Select an image, set a zoom level, choose effects, and configure them.

A Windows App SDK migration of the UWP Photo Editor sample app (C++/WinRT)

Article • 04/01/2023

This topic is a case study of taking the C++/WinRT UWP Photo Editor sample app, and migrating it to the Windows App SDK.

- Begin by cloning the UWP sample app's repo, and opening the solution in Visual Studio.

> **Important**
>
> For considerations and strategies for approaching the migration process, and how to set up your development environment for migrating, see **Overall migration strategy**.

Install tools for the Windows App SDK

To set up your development computer, see Install tools for the Windows App SDK.

> **Important**
>
> You'll find release notes topics along with the **Windows App SDK release channels** topic. There are release notes for each channel. Be sure to check any *limitations and known issues* in those release notes, since those might affect the results of following along with this case study and/or running the migrated app.

Create a new project

- In Visual Studio, create a new C++/WinRT project from the **Blank App, Packaged (WinUI 3 in Desktop)** project template. Name the project *PhotoEditor*, uncheck **Place solution and project in the same directory**. You can target the most recent release (not preview) of the client operating system.

> **Note**

We'll be referring to the UWP version of the sample project (the one that you cloned from its **repo**) as the *source* solution/project. We'll be referring to the Windows App SDK version as the *target* solution/project.

The order in which we'll migrate the code

MainPage is an important and prominent piece of the app. But if we were to begin by migrating that, then we'd soon realize that **MainPage** has a dependency on the **DetailPage** view; and then that **DetailPage** has a dependency on the **Photo** model. So for this walkthrough we'll take this approach.

- We'll begin by copying over the asset files.
- Then we'll migrate the **Photo** model.
- Next we'll migrate the **App** class (because that needs some members adding to it that **DetailPage** and **MainPage** will depend on).
- Then we'll begin migrating the views, starting with **DetailPage** first.
- And we'll finish up by migrating the **MainPage** view.

We'll be copying entire source code files

In this walkthrough we'll be copying over source code files using **File Explorer**. If you prefer to copy file *contents* over, then see the Appendix: copying the contents of the **Photo** model's files section at the end of this topic for an example of how you could do that for **Photo** (and you could then apply a similar procedure to other types in the project). That option does involve a lot more steps, though.

Copy asset files

1. In your clone of the source project, in **File Explorer**, locate the folder **Windows-appsample-photo-editor** > **PhotoEditor** > **Assets**. You'll find eight asset files in that folder. Select those eight files, and copy them to the clipboard.

2. Also in **File Explorer**, now locate the corresponding folder in the target project that you created. The path to that folder is **PhotoEditor** > **PhotoEditor** > **Assets**. Paste into that folder the asset files that you just copied, and accept the prompt to replace the seven files that already exist in the destination.

3. In your target project in Visual Studio, in **Solution Explorer**, expand the **Assets** folder. Add to that folder the existing `bg1.png` asset file that you just pasted. You

can hover the mouse pointer over the asset files. A thumbnail preview will appear for each, confirming that you've replaced/added the asset files correctly.

Migrate the Photo model

Photo is a runtime class that represents a photo. It's a *model* (in the sense of models, views, and viewmodels).

Copy Photo source code files

1. In your clone of the source project, in **File Explorer**, locate the folder **Windows-appsample-photo-editor** > **PhotoEditor**. In that folder you'll find the three source code files `Photo.idl`, `Photo.h`, and `Photo.cpp`; those files together implement the **Photo** runtime class. Select those three files, and copy them to the clipboard.

2. In Visual Studio, right-click the target project node, and click **Open Folder in File Explorer**. This opens the target project folder in **File Explorer**. Paste into that folder the three files that you just copied.

3. Back in **Solution Explorer**, with the target project node selected, make sure that **Show All Files** is toggled on. Right-click the three files that you just pasted, and click **Include In Project**. Toggle **Show All Files** off.

4. In the source project, in **Solution Explorer**, `Photo.h` and `.cpp` are nested under `Photo.idl` to indicate that they're generated from (dependent upon) it. If you like that arrangement, then you can do the same thing in the target project by manually editing `\PhotoEditor\PhotoEditor\PhotoEditor\PhotoEditor.vcxproj` (you'll first need to **Save All** in Visual Studio). Find the following:

   XML

   ```
   <ClInclude Include="Photo.h" />
   ```

   And replace it with this:

   XML

   ```
   <ClInclude Include="Photo.h">
     <DependentUpon>Photo.idl</DependentUpon>
   </ClInclude>
   ```

Repeat that for `Photo.cpp`, and save and close the project file. When you set focus back to Visual Studio, click **Reload**.

Migrate Photo source code

1. In `Photo.idl`, search for the namespace name `Windows.UI.Xaml` (which is the namespace for UWP XAML), and change that to `Microsoft.UI.Xaml` (which is the namespace for WinUI XAML).

> **Note**
>
> The Mapping UWP APIs to the Windows App SDK topic provides a mapping of UWP APIs to their Windows App SDK equivalents. The change we made above is an example of a namespace name change necessary during the migration process.

2. In `Photo.cpp`, add `#include "Photo.g.cpp"` to the existing include directives, immediately after `#include "Photo.h"`. This is one of the Folder and file name differences (C++/WinRT) to be aware of between UWP and Windows App SDK projects.

3. Make the following find/replacement (match case and whole word) in the contents of all of the source code in the files that you just copied and pasted.

   - `Windows::UI::Xaml` => `Microsoft::UI::Xaml`

4. From `pch.h` in the source project, copy the following includes, and paste them into `pch.h` in the target project. This is a subset of the header files included in the source project; these are just the headers we need to support the code we've migrated so far.

   C++/WinRT

   ```
   #include <winrt/Microsoft.UI.Xaml.Media.Imaging.h>
   #include <winrt/Windows.Storage.h>
   #include <winrt/Windows.Storage.FileProperties.h>
   #include <winrt/Windows.Storage.Streams.h>
   ```

5. Now confirm that you can build the target solution (but don't run yet).

Migrate the App class

No changes are necessary to the target project's `App.idl` and `App.xaml`. But we do need to edit `App.xaml.h` and App`.xaml.cpp` to add some new members to the **App** class. We'll do so in a way that lets us build after each section (with the exception of the last section, which is about **App::OnLaunched**).

Making the main window object available

In this step we'll make the change that's explained in Change Windows.UI.Xaml.Window.Current to App.Window.

In the target project, **App** stores the main window object in its private data member *window*. Later in the migration process (when we migrate the source project's use of **Window.Current**), it'll be convenient if that *window* data member is static; and is also made available via an accessor function. So we'll make those changes next.

- Since we're making *window* static, we'll need to initialize it in `App.xaml.cpp` instead of via the default member initializer that the code is currently using. Here are what those changes look like in `App.xaml.h` and `App.xaml.cpp`.

C++/WinRT

```
// App.xaml.h
...
struct App : AppT<App>
{
     ...
     static winrt::Microsoft::UI::Xaml::Window Window(){ return window; }
};

private:
     static winrt::Microsoft::UI::Xaml::Window window;
};
...

// App.xaml.cpp
...
winrt::Microsoft::UI::Xaml::Window App::window{ nullptr };
...
```

App::OnNavigationFailed

The *Photo Editor* sample app uses navigation logic to navigate between **MainPage** and **DetailPage**. For more info about Windows App SDK apps that need navigation (and those that don't), see Do I need to implement page navigation?.

So the members we'll migrate in the next few sections all exist to support navigation within the app.

1. Let's begin by migrating the **OnNavigationFailed** event handler. Copy the declaration and the definition of that member function from the source project, and paste it into the target project (in `App.xaml.h` and `App.xaml.cpp`).

2. In the code you pasted into `App.xaml.h`, change `Windows::UI::Xaml` to `Microsoft::UI::Xaml`.

App::CreateRootFrame

1. The source project contains a helper function named **App::CreateRootFrame**. Copy the declaration and the definition of that helper function from the source project, and paste it into the target project (in `App.xaml.h` and `App.xaml.cpp`).

2. In the code you pasted into `App.xaml.h`, change `Windows::UI::Xaml` to `Microsoft::UI::Xaml`.

3. In the code you pasted into `App.xaml.cpp`, change the two occurrences of `Window::Current()` to `window` (which is the name of the data member of the **App** class that we saw earlier).

App::OnLaunched

The target project already contains an implementation of the **OnLaunched** event handler. Its parameter is a constant reference to a **Microsoft::UI::Xaml::LaunchActivatedEventArgs**, which is correct for the Windows App SDK (contrast that to the source project, which uses **Windows::ApplicationModel::Activation::LaunchActivatedEventArgs**, which is correct for UWP).

- We just need to merge the two definitions (source and target) of **OnLaunched** so that **App::OnLaunched** in `App.xaml.cpp` in the target project looks like the listing below. Note that it uses `window` (instead of `Window::Current()`, like the UWP version does).

C++/WinRT

```
void App::OnLaunched(LaunchActivatedEventArgs const&)
{
     window = make<MainWindow>();
```

```
        Frame rootFrame = CreateRootFrame();
        if (!rootFrame.Content())
        {
            rootFrame.Navigate(xaml_typename<PhotoEditor::MainPage>());
        }

        window.Activate();
    }
```

The code above gives **App** a dependency on **MainPage**, so we won't be able to build from this point until we've migrated **DetailPage** and then **MainPage**. When we're able to build again, we'll say so.

Migrate the DetailPage view

DetailPage is the class that represents the photo editor page, where Win2D effects are toggled, set, and chained together. You get to the photo editor page by selecting a photo thumbnail on **MainPage**. **DetailPage** is a *view* (in the sense of models, views, and viewmodels).

Reference the Win2D NuGet package

To support code in **DetailPage**, the source project has a dependency on Microsoft.Graphics.Win2D. So we'll also need a dependency on Win2D in our target project.

- In the target solution in Visual Studio, click **Tools** > **NuGet Package Manager** > **Manage NuGet Packages for Solution...** > **Browse**. Make sure that **Include prerelease** is unchecked, and type or paste *Microsoft.Graphics.Win2D* into the search box. Select the correct item in search results, check the *PhotoEditor* project, and click **Install** to install the package.

Copy DetailPage source code files

1. In your clone of the source project, in **File Explorer**, locate the folder **Windows-appsample-photo-editor** > **PhotoEditor**. In that folder you'll find the four source code files `DetailPage.idl`, `DetailPage.xaml`, `DetailPage.h`, and `DetailPage.cpp`; those files together implement the **DetailPage** view. Select those four files, and copy them to the clipboard.

2. In Visual Studio, right-click the target project node, and click **Open Folder in File Explorer**. This opens the target project folder in **File Explorer**. Paste into that folder

the four files that you just copied.

3. Still in **File Explorer**, change the names of `DetailPage.h` and `DetailPage.cpp` to `DetailPage.xaml.h` and `DetailPage.xaml.cpp`, respectively. This is one of the Folder and file name differences (C++/WinRT) to be aware of between UWP and Windows App SDK projects.

4. Back in **Solution Explorer**, with the target project node selected, make sure that **Show All Files** is toggled on. Right-click the four files that you just pasted (and renamed), and click **Include In Project**. Toggle **Show All Files** off.

5. In the source project, in **Solution Explorer**, `DetailPage.idl` is nested under `DetailPage.xaml`. If you like that arrangement, then you can do the same thing in the target project by manually editing `\PhotoEditor\PhotoEditor\PhotoEditor.vcxproj` (you'll first need to **Save All** in Visual Studio). Find the following:

   ```
   XML
   <Midl Include="DetailPage.idl" />
   ```

   And replace it with this:

   ```
   XML
   <Midl Include="DetailPage.idl">
     <DependentUpon>DetailPage.xaml</DependentUpon>
   </Midl>
   ```

Save and close the project file. When you set focus back to Visual Studio, click **Reload**.

Migrate DetailPage source code

1. In `DetailPage.idl`, search for `Windows.UI.Xaml`, and change that to `Microsoft.UI.Xaml`.

2. In `DetailPage.xaml.cpp`, change `#include "DetailPage.h"` to `#include "DetailPage.xaml.h"`.

3. Immediately below that, add `#include "DetailPage.g.cpp"`.

4. For the call to the static **App::Window** method (which we're about to add) to compile, still in `DetailPage.xaml.cpp`, add `#include "App.xaml.h"` immediately

before `#include "Photo.h"`.

5. Make the following find/replacements (match case and whole word) in the contents of the source code in the files that you just copied and pasted.

   - In `DetailPage.xaml.h` and `.xaml.cpp`, `Windows::UI::Composition` => `Microsoft::UI::Composition`
   - In `DetailPage.xaml.h` and `.xaml.cpp`, `Windows::UI::Xaml` => `Microsoft::UI::Xaml`
   - In `DetailPage.xaml.cpp`, `Window::Current()` => `App::Window()`

6. From `pch.h` in the source project, copy the following includes, and paste them into `pch.h` in the target project.

   C++/WinRT

   ```
   #include <winrt/Windows.Graphics.Effects.h>
   #include <winrt/Microsoft.Graphics.Canvas.Effects.h>
   #include <winrt/Microsoft.Graphics.Canvas.UI.Xaml.h>
   #include <winrt/Microsoft.UI.Composition.h>
   #include <winrt/Microsoft.UI.Xaml.Input.h>
   #include <winrt/Windows.Graphics.Imaging.h>
   #include <winrt/Windows.Storage.Pickers.h>
   ```

7. Also, at the top of `pch.h`, immediately after `#pragma once`, add this:

   C++/WinRT

   ```
   // This is required because we are using std::min and std::max,
   otherwise
   // we have a collision with min and max macros being defined elsewhere.
   #define NOMINMAX
   ```

We can't build yet, but we will be able to after migrating **MainPage** (which is next).

Migrate the MainPage view

The main page of the app represents the view that you see first when you run the app. It's the page that loads the photos from the **Pictures Library**, and displays a tiled thumbnail view.

Copy MainPage source code files

1. Similar to what you did with **DetailPage**, now copy over `MainPage.idl`, `MainPage.xaml`, `MainPage.h`, and `MainPage.cpp`.

2. Rename the `.h` and `.cpp` files to `.xaml.h` and `.xaml.cpp`, respectively.

3. Include all four files in the target project like before.

4. In the source project, in **Solution Explorer**, `MainPage.idl` is nested under `MainPage.xaml`. If you like that arrangement, then you can do the same thing in the target project by manually editing `\PhotoEditor\PhotoEditor\PhotoEditor.vcxproj`. Find the following:

   XML

   ```
   <Midl Include="MainPage.idl" />
   ```

   And replace it with:

   XML

   ```
   <Midl Include="MainPage.idl">
     <DependentUpon>MainPage.xaml</DependentUpon>
   </Midl>
   ```

Migrate MainPage source code

1. In `MainPage.idl`, search for `Windows.UI.Xaml`, and change both occurrences to `Microsoft.UI.Xaml`.

2. In `MainPage.xaml.cpp`, change `#include "MainPage.h"` to `#include "MainPage.xaml.h"`.

3. Immediately below that, add `#include "MainPage.g.cpp"`.

4. For the call to the static **App::Window** method (which we're about to add) to compile, still in `MainPage.xaml.cpp`, add `#include "App.xaml.h"` immediately before `#include "Photo.h"`.

For the next step, we'll make the change that's explained in ContentDialog, and Popup.

5. So, still in `MainPage.xaml.cpp`, in the **MainPage::GetItemsAsync** method, immediately after the line `ContentDialog unsupportedFilesDialog{};`, add this line of code.

C++/WinRT

```
unsupportedFilesDialog.XamlRoot(this->Content().XamlRoot());
```

6. Make the following find/replacements (match case and whole word) in the contents of the source code in the files that you just copied and pasted.
   - In `MainPage.xaml.h` and `.xaml.cpp`, `Windows::UI::Composition` => `Microsoft::UI::Composition`
   - In `MainPage.xaml.h` and `.xaml.cpp`, `Windows::UI::Xaml` => `Microsoft::UI::Xaml`
   - In `MainPage.xaml.cpp`, `Window::Current()` => `App::Window()`
7. From `pch.h` in the source project, copy the following includes, and paste them into `pch.h` in the target project.

C++/WinRT

```
#include <winrt/Microsoft.UI.Xaml.Hosting.h>
#include <winrt/Microsoft.UI.Xaml.Media.Animation.h>
#include <winrt/Windows.Storage.Search.h>
```

Confirm that you can build the target solution (but don't run yet).

Update MainWindow

1. In `MainWindow.xaml`, delete the **StackPanel** and its contents, since we don't need any UI in **MainWindow**. That leaves only the empty **Window** element.
2. In `MainWindow.idl`, delete the placeholder `Int32 MyProperty;`, leaving only the constructor.
3. In `MainWindow.xaml.h` and `MainWindow.xaml.cpp`, delete the declarations and definitions of the placeholder **MyProperty** and **myButton_Click**, leaving only the constructor.

Migration changes needed for threading model difference

The two changes in this section are necessary due to a threading model difference between UWP and the Windows App SDK, as described in ASTA to STA threading model.

Here are brief descriptions of the causes of the issues, and then a way to resolve each.

MainPage

MainPage loads image files from your **Pictures** folder, calls StorageItemContentProperties.GetImagePropertiesAsync to get the image file's properties, creates a **Photo** model object for each image file (saving those same properties in a data member), and adds that **Photo** object to a collection. The collection of **Photo** objects is data-bound to a **GridView** in the UI. On behalf of that **GridView**, **MainPage** handles the ContainerContentChanging event, and for phase 1 that handler calls into a coroutine that calls StorageFile.GetThumbnailAsync. This call to **GetThumbnailAsync** results in messages being pumped (it doesn't return immediately, and do *all* of its work async), and that causes reentrancy. The result is that the **GridView** has its **Items** collection changed while layout is taking place, and that causes a crash.

If we comment out the call to **StorageItemContentProperties::GetImagePropertiesAsync**, then we don't get the crash. But the real fix is to make the **StorageFile.GetThumbnailAsync** call be explicitly async by cooperatively awaiting **wil::resume_foreground** immediately before calling **GetThumbnailAsync**. This works because **wil::resume_foreground** schedules the code that follows it to be a task on the **DispatcherQueue**.

Here's the code to change:

C++/WinRT

```
// MainPage.xaml.cpp
IAsyncAction MainPage::OnContainerContentChanging(ListViewBase sender,
ContainerContentChangingEventArgs args)
{
    ...
    if (args.Phase() == 1)
    {
        ...
        try
        {
            co_await wil::resume_foreground(this->DispatcherQueue());
            auto thumbnail = co_await impleType-
>GetImageThumbnailAsync(this->DispatcherQueue());
            image.Source(thumbnail);
        }
        ...
    }
}
```

Photo

The **Photo::ImageTitle** property is data-bound to the UI, so the UI calls into the accessor function for that property whenever it needs its value. But when we try to access **ImageProperties.Title** from that accessor function on the UI thread, we get an access violation.

So instead, we can just access that **Title** one-time, from the constructor of **Photo**, and store it in the *m_imageName* data member if it's not empty. Then in the **Photo::ImageTitle** accessor function we need only to access the *m_imageName* data member.

Here's the code to change:

```
// Photo.h
...
Photo(Photo(Windows::Storage::FileProperties::ImageProperties const& props,
    ...
    ) : ...
{
    if (m_imageProperties.Title() != L"")
    {
        m_imageName = m_imageProperties.Title();
    }
}
...
hstring ImageTitle() const
{
    return m_imageName;
}
...
```

Those are the last of the changes we need to make to migrate the *Photo Editor* sample app. In the **Test the migrated app** section we'll confirm that we've correctly followed the steps.

Known issues

App type issue (affects only Preview 3)

If you followed along with this case study using the project template from the VSIX for Windows App SDK version 1.0 Preview 3, then you'll need to make a small correction to `PhotoEditor.vcxproj`. Here's how to do that.

In Visual Studio, in **Solution Explorer**, right-click the project node, and click **Unload Project**. Now `PhotoEditor.vcxproj` is open for editing. As the first child of **Project**, add a **PropertyGroup** element like this:

XML

```
<Project ... >
    <PropertyGroup>
        <EnableWin32Codegen>true</EnableWin32Codegen>
    </PropertyGroup>
    <Import ... />
...
```

Save and close `PhotoEditor.vcxproj`. Right-click the project node, and click **Reload Project**. Now rebuild the project.

Test the migrated app

Now build the project, and run the app to test it. Select an image, set a zoom level, choose effects, and configure them.

Appendix: copying the contents of the Photo model's files

As we discussed earlier, you have the option to copy over source code *files* themselves, or the *contents* of source code files. We've already shown how to copy over source code *files* themselves. So this section gives an example of copying file *contents*.

In the source project in Visual Studio, locate the folder **PhotoEditor (Universal Windows)** > **Models**. That folder contains the files `Photo.idl`, `Photo.h`, and `Photo.cpp`, which together implement the **Photo** runtime class.

Add the IDL, and generate stubs

In your target project in Visual Studio, add a new **Midl File (.idl)** item to the project. Name the new item `Photo.idl`. Delete the default contents of `Photo.idl`.

From the source project in Visual Studio, copy the contents of **Models** > `Photo.idl`, and paste them into the `Photo.idl` file that you just added to your target project. In the code you pasted, search for `Windows.UI.Xaml`, and change that to `Microsoft.UI.Xaml`.

Save the file.

> **ⓘ Important**
>
> We're about to perform a build of your target solution. The build won't run to completion at this point, but it will get far enough to do necessary work for us.

Now build the target solution. Even though it won't complete, building is necessary now because it'll generate the source code files (stubs) that we need to get started implementing the **Photo** model.

In Visual Studio, right-click the target project node, and click **Open Folder in File Explorer**. This opens the target project folder in **File Explorer**. There, navigate into the `Generated Files\sources` folder (so you'll be in `\PhotoEditor\PhotoEditor\PhotoEditor\Generated Files\sources`). Copy the stub files `Photo.h` and `.cpp`, and paste them into the project folder, which is now up two folder levels in `\PhotoEditor\PhotoEditor\PhotoEditor`.

Back in **Solution Explorer**, with the target project node selected, make sure that **Show All Files** is toggled on. Right-click the stub files that you just pasted (`Photo.h` and `.cpp`), and click **Include In Project**. Toggle **Show All Files** off.

You'll see a `static_assert` at the top of the contents of `Photo.h` and `.cpp`, which you'll need to delete.

Confirm that you can build again (but don't run yet).

Migrate code into the stubs

Copy the contents of `Photo.h` and `.cpp` from the source project into the target project.

From here, the remaining steps to migrate the code that you copied are the same as those given in the Migrate **Photo** source code section.

Additional migration guidance

Article • 06/24/2024

This topic contains additional migration guidance not categorized into a feature area in the feature area guides.

Conditional compilation

The info in this section might be useful if you plan to use the same source code file in both a UWP and a Windows App SDK project.

In C# source code in a Windows App SDK project, you can use preprocessor directives with the **WINDOWS_UWP** symbol to perform conditional compilation.

C#

```
#if !WINDOWS_UWP
    // Win32/Desktop code, including Windows App SDK code
#else
    // UWP code
#endif
```

In C++/WinRT source code in a Windows App SDK project, you can use preprocessor directives with **WINAPI_FAMILY_PC_APP** to do the same thing. Or you could use **WINAPI_FAMILY_DESKTOP_APP** instead. A comment in the `winapifamily.h` header file indicates that **WINAPI_FAMILY_APP** should be considered deprecated.

C++/WinRT

```
#if (WINAPI_FAMILY == WINAPI_FAMILY_DESKTOP_APP)
    // Win32/Desktop code, including Windows App SDK code
#else
    // UWP code
#endif
```

You can also use conditional compilation in XAML markup.

XAML

```
<Application
    ...
    xmlns:nouwp="condition:!WINDOWS_UWP"
    mc:Ignorable="nouwp">
    <Application.Resources>
```

```
        <ResourceDictionary>
            <ResourceDictionary.MergedDictionaries>
                <!--Not Needed for UWP-->
                <nouwp:XamlControlsResources
xmlns="using:Microsoft.UI.Xaml.Controls" />
                 <!--Other merged dictionaries here-->
            </ResourceDictionary.MergedDictionaries>
             <!--Other app resources here-->
        </ResourceDictionary>
    </Application.Resources>
</Application>
```

Also see Conditional compilation.

Debugging

During the migration process, you might find your app in a state where your XAML markup has references to XAML resource keys, but you haven't yet defined those keys. Such a condition results in a run-time crash that might not be straightforward to debug. But in a debug build, messages about missing resource keys appear in Visual Studio via debug output in the **Output** pane. So run your app under the debugger, and watch out for such messages.

Unregistering an event handler (C++/WinRT)

In a C++/WinRT project, you can manually revoke (unregister) an event handler such as **SizeChanged** (for more details, and code examples, see Revoke a registered delegate). But an alternative to manually revoking—and one that you could consider if you're having problems with manually revoking—is to use a C++/WinRT auto event revoker. Again, more details and code examples in Revoke a registered delegate.

Migrate from UWP to the Windows App SDK with the .NET Upgrade Assistant

Article • 10/05/2023

The .NET Upgrade Assistant (see Overview of the .NET Upgrade Assistant) is a Visual Studio extension (recommended), and a command-line tool, that can assist with migrating a C# Universal Windows Platform (UWP) app to a WinUI 3 app that uses the Windows App SDK.

Our roadmap for UWP support in the .NET Upgrade Assistant includes further tooling improvements, and adding migration support for new features. If you find issues related to the .NET Upgrade Assistant, then you can file them within Visual Studio by selecting **Help** > **Send Feedback** > **Report a Problem**.

Also see the Upgrade Assistant GitHub repository. Options for running the tool on the command-line are documented there.

Install the .NET Upgrade Assistant

You can install the .NET Upgrade Assistant as a Visual Studio extension or as a .NET command-line tool. For more info, see Install the .NET Upgrade Assistant.

Summary

When you use the .NET Upgrade Assistant to migrate your UWP app, here are the high-level steps and stages in the migration process that the tool carries out.

- Optionally copies your project, and migrates the copy; leaving your original project unchanged.
- Optionally migrates your project in-place (in the same folders and files, without renaming folders); and doesn't make a copy.
- Upgrades your project from the .NET Framework project format to the latest .NET SDK project format.
- Cleans up NuGet package references. In addition to the packages referenced by your app, the `packages.config` file contains references to the dependencies of those packages. For example, if you added reference to package **A**, which depends on package **B**, then both packages would be referenced in the `packages.config` file. In the new project system, only the reference to package **A** is required. So this step analyzes the package references, and removes those that aren't required. Your

app is still referencing .NET Framework assemblies. Some of those assemblies might be available as NuGet packages. So this step analyzes those assemblies, and references the appropriate NuGet package.
- Targets .NET 6, and the Windows App SDK.
- Changes the target framework moniker (TFM) (see Target frameworks in SDK-style projects) from .NET Framework to the suggested SDK. For example, `net6.0-windows`.
- Migrates your UWP source code from WinUI 2 to WinUI 3, performing source-specific code changes.
- Adds/updates any template, config, and code files. For example, adding necessary publishing profiles, `App.xaml.cs`, `MainWindow.xaml.cs`, `MainWindow.xaml`, and others.
- Update namespaces, and adds **MainPage** navigation.
- Attempts to detect and fix APIs that are different between UWP and the Windows App SDK, and uses **Task List** TODOs to mark APIs that are no longer supported.

As it runs, the tool also aims to provide migration guidance in the form of warning messages within the tool's output, and **Task List** TODOs in the form of comments within your project's source code (for example, for cases where completely automated migration of your UWP source code isn't possible). A typical **Task List** TODO includes a link to a topic in this migration documentation. As the developer, you're always in control of the migration process.

> **Tip**
>
> To see all of the TODOs that the tool has generated, look in the **Task list** in Visual Studio.

> **Note**
>
> After the tool has finished running, there are some follow-up steps you can choose to do if needed. You can move your code from `App.xaml.old.cs` to `App.xaml.cs`; and you can restore `AssemblyInfo.cs` from the backup that the tool creates.

What the tool supports

This release of the .NET Upgrade Assistant is currently in preview, and is receiving frequent updates. The tool currently supports only the C# programming language; not

C++. And in most cases with this release, your project will require additional effort from you to complete the migration.

The tool aims to migrate your project and code so that it compiles. But some features require you to investigate and fix them (via **Task List** TODOs). For more information about what to consider before migrating, see What's supported when migrating from UWP to WinUI 3.

Because of the following limitations of the current release of the .NET Upgrade Assistant, you might choose to wait for a future release before migrating your app:

- Migrating from **ApplicationView** APIs isn't supported.
- Migrating from **AppWindow**-related APIs isn't supported.

Where possible, the tool tries to generate a warning; and it intentionally causes your code not to compile until you change it.

- Custom views aren't supported. For example, you won't receive a warning or a fix for a custom dialog that extends **MessageDialog**, and calls an API incorrectly.
- Windows Runtime Components aren't supported.

- Multi-window apps might not be migrated correctly.
- A project that follows a non-standard file structure (such as `App.xaml` and `App.xaml.cs` not being in the root folder) might not be migrated correctly.

The Upgrade Assistant GitHub repository documents troubleshooting tips and known issues. If you find any issues while using the tool, please report them in that same GitHub repository, tagging them with an area tag of `UWP`. We appreciate it!

> **Note**
>
> For guidance about the migration process—and the differences between UWP and Windows App SDK features and APIs—see Migrate from UWP to the Windows App SDK.

> **Tip**
>
> You can see what version of the tool you have by issuing the command `upgrade-assistant --version`.

Test drive the tool with the UWP PhotoLab sample

Let's take the .NET Upgrade Assistant for a test-drive.

As source material, we'll be migrating the UWP PhotoLab sample application. PhotoLab is a sample app for viewing and editing image files. It demonstrates XAML layout, data binding, and UI customization features.

> **Note**
>
> You can see a case study of the PhotoLab sample being fully manually migrated in A Windows App SDK migration of the UWP PhotoLab sample app.

1. Begin by cloning or downloading the PhotoLab sample source code from the link above.

> **Tip**
>
> Be aware that after we've used the tool to automate the migration of the app, additional manual effort will be needed to complete the migration.

1. Open the PhotoLab solution in Visual Studio.
2. Having installed the .NET Upgrade Assistant extension (see Install the .NET Upgrade Assistant earlier in this topic), right-click on the project in **Solution Explorer**, and click **Upgrade**.
3. Choose the **Upgrade project to a newer .NET version** option.
4. Choose the **In-place project upgrade** option.
5. Choose a target framework.
6. Click **Upgrade selection**.
7. The .NET Upgrade Assistant runs, and uses the Visual Studio **Output** window to print out info and status as it goes.

You can monitor the progress bar until the upgrade operation completes.

Code migration for the **PhotoLab** sample app includes:

- Changes to Content Dialog and File Save picker APIs.
- XAML update for the Animations package.
- Showing warning messages, and adding **Task List** TODOs in `DetailPage.xaml`, `DetailPage.xaml.cs`, and `MainPage.xaml.cs` for custom back button.
- Implementing the back button functionality and adding a **Task List** TODO to customize XAML button.
- A link to documentation is provided that you can use to learn more about back button implementation.

The version numbers in your resulting `.csproj` will be slightly different, but essentially it will look like this (with some of the build configuration property groups removed for brevity):

XML

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
    <Platform Condition=" '$(Platform)' == '' ">x86</Platform>
    <OutputType>WinExe</OutputType>
    <DefaultLanguage>en-US</DefaultLanguage>
    <TargetPlatformMinVersion>10.0.17763.0</TargetPlatformMinVersion>
    <RuntimeIdentifiers>win-x86;win-x64;win-arm64</RuntimeIdentifiers>
    <UseWinUI>true</UseWinUI>
    <ApplicationManifest>app.manifest</ApplicationManifest>
    <EnableMsixTooling>true</EnableMsixTooling>
    <Platforms>x86;x64;arm64</Platforms>
    <PublishProfile>win10-$(Platform).pubxml</PublishProfile>
  </PropertyGroup>
  <ItemGroup>
    <AppxManifest Include="Package.appxmanifest">
      <SubType>Designer</SubType>
    </AppxManifest>
  </ItemGroup>
  <ItemGroup>
    <PackageReference Include="Microsoft.WindowsAppSDK" Version="1.1.0" />
    <PackageReference Include="Microsoft.Graphics.Win2D" Version="1.0.0.30"
/>
    <PackageReference
Include="Microsoft.DotNet.UpgradeAssistant.Extensions.Default.Analyzers"
Version="0.4.346201">
      <PrivateAssets>all</PrivateAssets>
    </PackageReference>
    <PackageReference Include="Microsoft.Windows.Compatibility"
Version="6.0.0" />
    <PackageReference Include="CommunityToolkit.WinUI.UI.Animations"
Version="7.1.2" />
  </ItemGroup>
  <ItemGroup>
    <Compile Remove="App.xaml.old.cs" />
```

```
  </ItemGroup>
  <ItemGroup>
    <None Include="App.xaml.old.cs" />
  </ItemGroup>
</Project>
```

As you can see, the project is now referencing the Windows App SDK, WinUI 3, and .NET 6. Now that **PhotoLab** has been migrated, you can take advantage of all of the new features that WinUI 3 apps have to offer, and grow your app with the platform.

Also, the .NET Upgrade Assistant adds analyzers to the project that assist with continuing with the upgrade process. For example, the **Microsoft.DotNet.UpgradeAssistant.Extensions.Default.Analyzers** NuGet package.

Follow-up manual migration

At this point you can open the migrated **PhotoLab** solution or project, and see the changes that have been made in the source code. The project needs a little more work to finish hooking things up before the WinUI 3 version builds, runs, and behaves like the UWP version.

See the **Task List** in Visual Studio (**View** > **Task List**) for TODOs that you should action to manually complete the migration.

It's possible that the UWP (.NET Framework) version of your app contained library references that your project isn't actually using. You'll need to analyze each reference, and determine whether or not it's required. The tool might also have added or upgraded a NuGet package reference to the wrong version.

The Upgrade Assistant doesn't edit the `Package.appxmanifest`, which will need some edits in order for the app to launch:

1. Add this namespace on the root <Package> element:

```
xmlns:rescap="http://schemas.microsoft.com/appx/manifest/foundation/windows10/restrictedcapabilities"
```

2. Edit the <Application> element from `EntryPoint="appnamehere.App"` to `EntryPoint="$targetentrypoint$"`

3. Replace any specified `Capability` with this:

XML

```
<rescap:Capability Name="runFullTrust" />
```

In your `.csproj` file, you might need to edit the project file to set `<OutputType>WinExe</OutputType>` and `<UseMaui>False</UseMaui>`.

To use many of the XAML controls, ensure that your `app.xaml` file includes the `<XamlControlsResources>`, such as in this example:

XML

```
<Application.Resources>
    <ResourceDictionary>
        <ResourceDictionary.MergedDictionaries>
            <XamlControlsResources xmlns="using:Microsoft.UI.Xaml.Controls"
/>
            <!-- Other merged dictionaries here -->
        </ResourceDictionary.MergedDictionaries>
        <!-- Other app resources here -->
    </ResourceDictionary>
</Application.Resources>
```

Troubleshooting tips

There are several known problems that can occur when using the .NET Upgrade Assistant. In some cases, these problems are with the try-convert tool that the .NET Upgrade Assistant uses internally.

But for more troubleshooting tips and known issues, see the Upgrade Assistant GitHub repository.

Modernize your desktop apps

Article • 10/24/2022

Windows 11 and Windows 10 offer many features you can use to deliver a modern experience in your desktop apps. Most of these features are available as modular components that you can adopt in your desktop apps at your own pace without having to rewrite your application for a different platform. You can enhance your existing desktop apps by choosing which Windows features to adopt.

This topic describes the features that you can use in your desktop apps today. For a tutorial that demonstrates how to modernize an existing app to use many of the features described in this topic, see the Modernize a WPF app tutorial.

> **Note**
>
> Do you need assistance migrating desktop apps to Windows 10 or later? The App Assure service provides direct, no-cost support to developers who are porting their apps to Windows 10 and later versions. This program is available to all ISVs and eligible enterprises. For more details on eligibility and about the program itself, visit /fasttrack/win-10-app-assure-assistance-offered. To get started now, submit your request.

Apply Windows 11 features

Windows 11 marks a visual evolution of the Windows operating system, and introduces new features that improve app fundamentals and user experience. Many of these features are enabled by default for apps, but desktop apps may require updates to integrate with some new features. These features include rounded corners of top-level windows, snap layouts, and the updated context menu in File Explorer.

For more information, see Top 11 things you can do to make your app great on Windows 11.

Windows App SDK

The Windows App SDK is a set of new developer components and tools that represent the next evolution in the Windows app development platform. The Windows App SDK provides a unified set of APIs and tools that can be used in a consistent way by any desktop app on Windows 11 and many versions of Windows 10. You can use project

templates to create new desktop apps that use the Windows App SDK with a WinUI 3-based UI, or you can use the Windows App SDK in existing desktop apps.

For more information, see Windows App SDK.

WinUI

WinUI is a native user experience framework for both Windows desktop and UWP applications. WinUI started as a toolkit that provided new and updated versions of WinRT XAML controls for UWP apps that target down-level versions of Windows. The latest version, WinUI 3, has grown in scope and is now the modern native UI platform for Windows desktop apps.

You can use WinUI in the following ways in desktop apps:

- Use WinUI 3 to create desktop apps (see Create your first WinUI 3 project) with an entirely WinUI 3-based user interface. WinUI 3 is one of many features provided by the Windows App SDK.
- You can update existing WPF, Windows Forms, and C++ desktop (Win32) apps with XAML Islands and host WinUI 2 controls.

For more information, see WinUI.

Windows Runtime APIs

You can call many Windows Runtime APIs directly in your WPF, Windows Forms, or C++ desktop app to integrate modern experiences that light up for users. For example, you can call Windows Runtime APIs to add toast notifications to your desktop app.

For more information, see Use Windows Runtime APIs in desktop apps.

MSIX deployment

MSIX is a modern Windows app package format that provides a universal packaging experience for all Windows apps, including UWP, WPF, Windows Forms and Win32 apps. MSIX brings together the best aspects of MSI, .appx, App-V and ClickOnce installation technologies to provide a modern and reliable packaging experience.

Packaging your desktop Windows apps in MSIX packages gets you access to a robust installation and updating experience, a managed security model with a flexible capability system, support for the Microsoft Store, enterprise management, and many custom distribution models.

For more information, see Building an MSIX package from your code.

Use MSIX framework packages dynamically at run time

The *dynamic dependencies* feature in the Windows App SDK and in the Windows 11 OS enables your apps to reference MSIX framework packages at run time. This feature is intended to be used primarily by unpackaged desktop apps to call APIs that are provided by MSIX framework packages.

For more information, see Use MSIX framework packages dynamically from your desktop app.

.NET

.NET (previously known as .NET Core) supports Windows desktop apps, including WinUI 3 apps created with the Windows App SDK (see Create your first WinUI 3 project). .NET also supports Windows Presentation Foundation (WPF) and Windows Forms (WinForms) apps. You can run new and existing Windows desktop apps on .NET, and enjoy all the benefits that .NET has to offer.

For more information, see What's new in .NET 6.

Host WinRT XAML controls (XAML Islands)

Starting with the Windows 10, version 1903, you can add UWP XAML controls directly to any UI element in a WPF, Windows Forms, or C++ desktop app that is associated with a window handle (HWND). This means that you can fully integrate the latest UWP features such as Windows Ink and controls that support the Fluent Design System into windows and other display surfaces in your desktop apps. This developer scenario is sometimes called *XAML islands*.

For more information, see WinRT XAML controls in desktop apps

Use the Visual layer in desktop apps

You can now use Windows Runtime APIs in non-UWP desktop apps to enhance the look, feel, and functionality of your WPF, Windows Forms, and C++ desktop apps, and take advantage of the latest Windows UI features that are only available via UWP. This is

useful when you need to create custom experiences that go beyond the built-in WinRT XAML controls you can host by using XAML Islands.

For more information, see Modernize your desktop app using the Visual layer.

Additional features available to apps with package identity

Some modern Windows experiences are available only to desktop apps that have package identity at runtime. These features include certain Windows Runtime APIs, package extensions, and UWP components. For more info, see Features that require package identity.

WinRT XAML controls optimized for desktop apps

Whether you're building a UWP app that exclusively targets the desktop device family or you want to use WinRT XAML controls in a WPF, Windows Forms, or C++ desktop app, the following new and updated WinRT XAML controls are designed to offer desktop-optimized experiences with the Fluent Design System. These controls were introduced in Windows 10, version 1809 (the October 2018 Update, or version 10.0.17763).

Expand table

Control	Description
MenuBar	Provides a quick and simple way to expose a set of commands for apps that might need more organization or grouping than a **CommandBar** allows.
DropDownButton	Shows a chevron as a visual indicator that it has an attached flyout that contains more options.
SplitButton	Provides a button has two parts that can be invoked separately. One part behaves like a standard button and invokes an immediate action. The other part invokes a flyout that contains additional options that the user can choose from.
ToggleSplitButton	Provides a button has two parts that can be invoked separately. One part behaves like a toggle button that can be on or off. The other part invokes a flyout that contains additional options that the user can choose from.
CommandBarFlyout	Lets you show common user tasks in the context of an item on your UI canvas.

Control	Description
ComboBox	You can now make a combo box editable so the user can enter values that aren't listed in the control.
TreeView	You can now configure a tree view to enable data binding, item templates, and drag and drop.
DataGridView	Provides a flexible way to display a collection of data in rows and columns. This control is available in the Windows Community Toolkit.

Other technologies for modern desktop apps

Microsoft Graph

Microsoft Graph is a collection of APIs you can use to build apps for organizations and consumers that interact with the data of millions of users. Microsoft Graph exposes REST APIs and client libraries to access data on the following:

- Azure Active Directory
- Microsoft 365 Office apps: SharePoint, OneDrive, Outlook/Exchange, Microsoft Teams, OneNote, Planner, and Excel
- Enterprise Mobility and Security services: Identity Manager, Intune, Advanced Threat Analytics, and Advanced Threat Protection.
- Windows services: activities and devices

For more information, see the Microsoft Graph docs.

Adaptive Cards

Adaptive Cards is an open, cross-platform framework that you can use to exchange card-based UI content in a common and consistent way across devices and platforms.

For more information, see the Adaptive Cards docs.

Top 11 things you can do to make your app great on Windows 11

Article • 03/06/2025

Windows 11 marks a visual evolution of the Windows operating system. As Windows moves forward, customers continue to set a higher bar for app experiences, too. We see these customer expectations manifest primarily in three areas: *app fundamentals*, *user experience*, and *added security*.

- *App fundamentals* - good performance on low-cost, highly mobile device form factors, and hassle-free app lifecycle and state rehydration/roaming.
- *User experience* - the ability to work naturally with a complete range of inputs, design and interaction patterns that look and feel at home on current and future devices, and support for modern windowing workflows and shell integration points.
- *Added security* - deploying apps on a secure platform that protects user data and privacy, and the ability to integrate features like Windows Hello and Passkeys to provide a more secure experience for users.

With entirely new visuals signaling change, signature experiences that showcase the best of Windows and Microsoft together, and a completely new Store with more apps, Windows 11 is positioned as the Windows for "what's next".

Great apps on Windows meet these customer expectations for app fundamentals, modern user experience, and added security, and we're investing in the native Windows platform to make it easier for your apps to achieve greatness through WinUI, MSIX, and the Windows App SDK family of APIs. This document provides an overview what you need to do to make your app look and behave great so that users feel like your app was made for Windows 11.

Here are the top ~~10~~ 11 things you can do to make your app shine on Windows 11.

1. Test your app to be compatible with Windows 11

Users expect solid fundamentals from any app they install on their device. They expect the app to just work when they upgrade it or migrate to a new version of the operating system. Compatibility testing helps to make sure there is no difference in functionality for your apps after upgrade and helps increase customer satisfaction with a well-tested product.

Test your app to be compatible with Windows 11

Microsoft is committed to ensuring your apps work on the latest versions of our software and Windows 11 has been built with compatibility in mind. Our promise states that apps that worked on Windows 7/8.1/10 will work on Windows 11. If you experience any issues with your apps, Microsoft will help you identify the issue at no cost so that you can then fix the issue. Visit the App Assure page and sign in to submit your request for assistance from a dedicated App Assure Manager.

2. Have a discoverable and easy to understand privacy policy

An easily discoverable and understandable privacy notice increases user trust and confidence in your application.

Your privacy policy must:

- Inform users of the personal information accessed, collected, or transmitted by your product.
  - How that information is used, stored, and secured.
  - Indicate the types of parties to whom that information is disclosed.
- Describe the controls that users have over the use and sharing of their information and how they may access their information.
- Comply with applicable laws and regulations.
- Be kept up-to-date as you add new features and functionality to your product.

Microsoft Privacy Statement

3. Make your app accessible and inclusive

Inclusive design creates better products for everyone. To make sure your app is accessible and inclusive, consider what improved functionality and usability means in relation to:

- People with disabilities (both temporary and permanent).
- Personal preferences.
- Specific work styles.
- Situational constraints (such as shared work spaces, driving, cooking, glare, and so on).

Some common solutions include providing information in alternative formats (such as captions on a video) or enabling the use of assistive technologies (such as screen

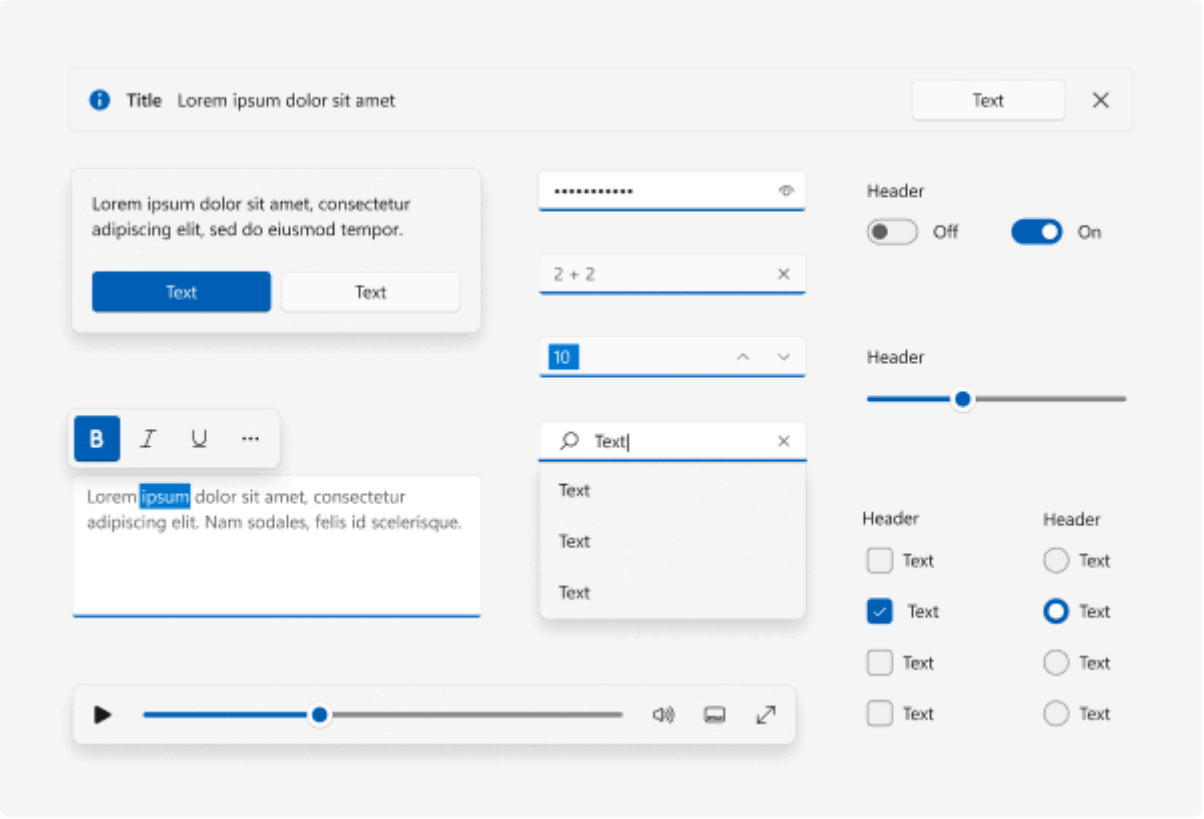
readers).

Applications designed with accessibility in mind are easier to maintain, update, and redesign. In addition to helping your app reach people with disabilities, factoring in accessibility can reduce the cost of maintaining your app.

Accessibility in Windows

4. Use the latest common controls

Windows 11 brings beautiful UI innovations to the Windows operating system that you can leverage in your apps. Common controls are one way that you can utilize these updates immediately. Use the latest common controls whenever possible to get the benefits of compatibility and accessibility for free. And these common controls are more cost effective than building your own custom controls when you factor in maintenance and testing costs.



Desktop apps (Win32)

- Use WinUI 3 in Windows App SDK 1.1 or greater to create a Win32 application that can leverage the modern common controls.
- To evaluate the controls, check out the WinUI 3 Gallery (*main branch*).
- Win32 controls that use UXTheme will automatically get a "repaint" of the Light theme for select rejuvenated control visuals. Be sure to test for any issues. For

those surfaces that do not get updated automatically, manually update the visuals so that they look coherent with the rest of the update, if possible.

UWP apps

- If your app uses UWP XAML or WinUI, update to use WinUI 2.6 or greater. WinUI provides new styles for both UWP XAML and WinUI controls, and the default styles have been updated with rejuvenated visuals and animation by default.
- See the documentation for a list of supported controls.
- Use the WinUI 2 Gallery (*winui 2 branch*) to evaluate the controls.

WebView and other platforms

- Individual WebView surfaces need to do work to adopt the style manually. We will not provide centralized styles, but the design toolkits and WinUI 2 Gallery can be used to copy the styles.

5. Use the latest design materials (Acrylic and Mica)

We are introducing a new material called *Mica* that lets the user's desktop background shine through your app. Mica is a very performant material that is meant to be used on long-lived UI surfaces like TitleBar to communicate the active or inactive state of the app. Mica is a texture that creates visual delight while saving battery life.

- Mica is to be used on the base layer of the app's UI to communicate the active state of the app; it falls back to a solid color when the app does not have focus. Thus, we recommend use of Mica on the TitleBar's background.
- Some controls, like NavigationView, already come built with the default behavior.

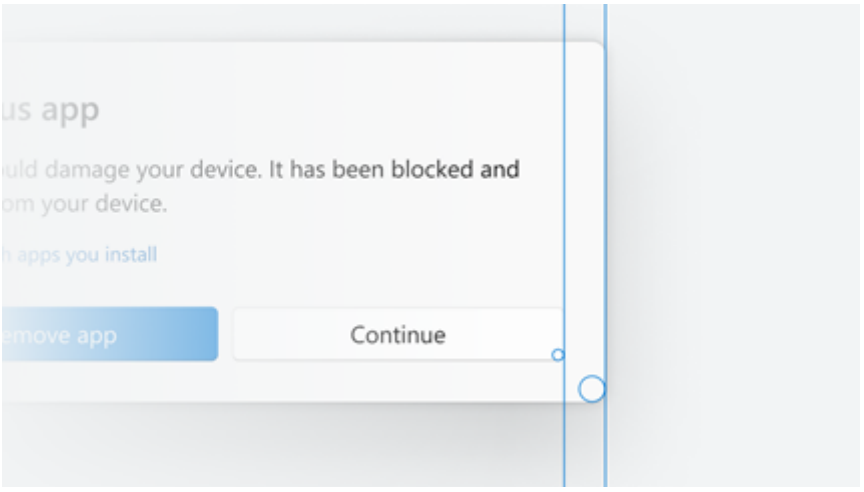
- When an app that uses Mica runs in Windows 10 or down-level, it will degrade gracefully (Mica will fallback to a solid color).
- Mica is to be used on long-lived surfaces, unlike Acrylic, which is to be used on transient surfaces.
- If you are using Acrylic material, follow the existing Acrylic guidance as we have updated the colors to be more vibrant.

Mica guidance, Acrylic guidance

6. Use rounded corners for your windows and support snap layouts

App windows have new features like rounded corners and a menu with snap layouts that your app will automatically receive in most cases. If you've customized your window or title bar, you might need to do some work to make sure these new features are supported.

We rounded the corners of window borders in Windows 11. Our user research team found that rounded geometry psychologically provides a feeling of safety and makes the app's UI much easier to scan. This makes users feel less intimidated and the app feel more engaging. The amount of rounding was also carefully chosen. We worked across the company and user research to balance between feeling professional and being softer and more inviting.



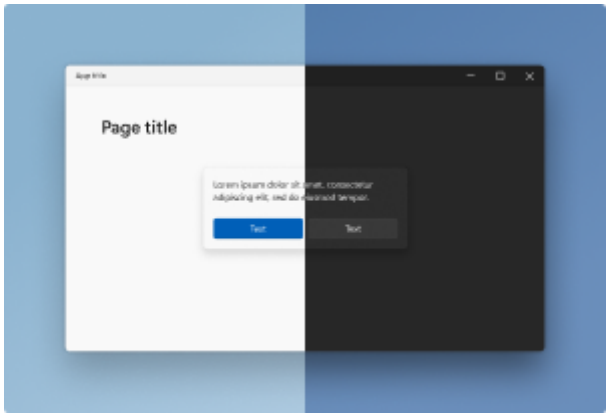
Snap layouts are a new Windows 11 feature to help introduce users to the power of window snapping. Snap layouts are easily accessible by hovering the mouse over a window's maximize button or pressing Win + Z. After invoking the menu that shows the available layouts, users can click on a zone in a layout to snap a window to that particular zone and then use Snap Assist to finish building an entire layout of windows. Snap layouts are tailored to the current screen size and orientation, including support

for three side-by-side windows on large landscape screens and top/bottom stacked windows on portrait screens.

- Most apps will automatically receive rounded corners and support for the menu with snap layouts, but in some cases you might need to do a little work to get them:
  - Allow the system to draw your border and shadow.
  - If you need to draw your own border and shadow:
    - Call our rounding API to opt in. See Apply rounded corners in desktop apps for Windows 11.
    - Use our APIs to have the platform draw and implement the caption buttons. See Support snap layouts for desktop apps on Windows 11.
- You will get these features automatically if you use UWP or you adopt Windows App SDK windowing to:
  - Configure the style of your window using the pre-defined templates.
  - Customize the title bar of your windows.

7. Support Dark and Light themes

We support Light and Dark themes, which is a great way to let the user express their personality. We are updating the color tones to be softer on the eyes by avoiding pure white and black, which makes the colors much more delightful. Dark theme support is also a great to make your app more accessible and attractive for different types of users.



- The color palette of WinUI is being updated to feel lighter (use WinUI 2.6 or greater). If your apps have hardcoded custom colors, you may need to make updates to match the overall color theory, regardless of technology.
- If you are using UXTheme based Win32 surfaces, the Light theme will have rejuvenated controls (for example, rounded buttons). You should test your apps to validate that local styling does not override updated global defaults. (For Win32 apps, see Support Dark and Light themes in Win32 apps.)

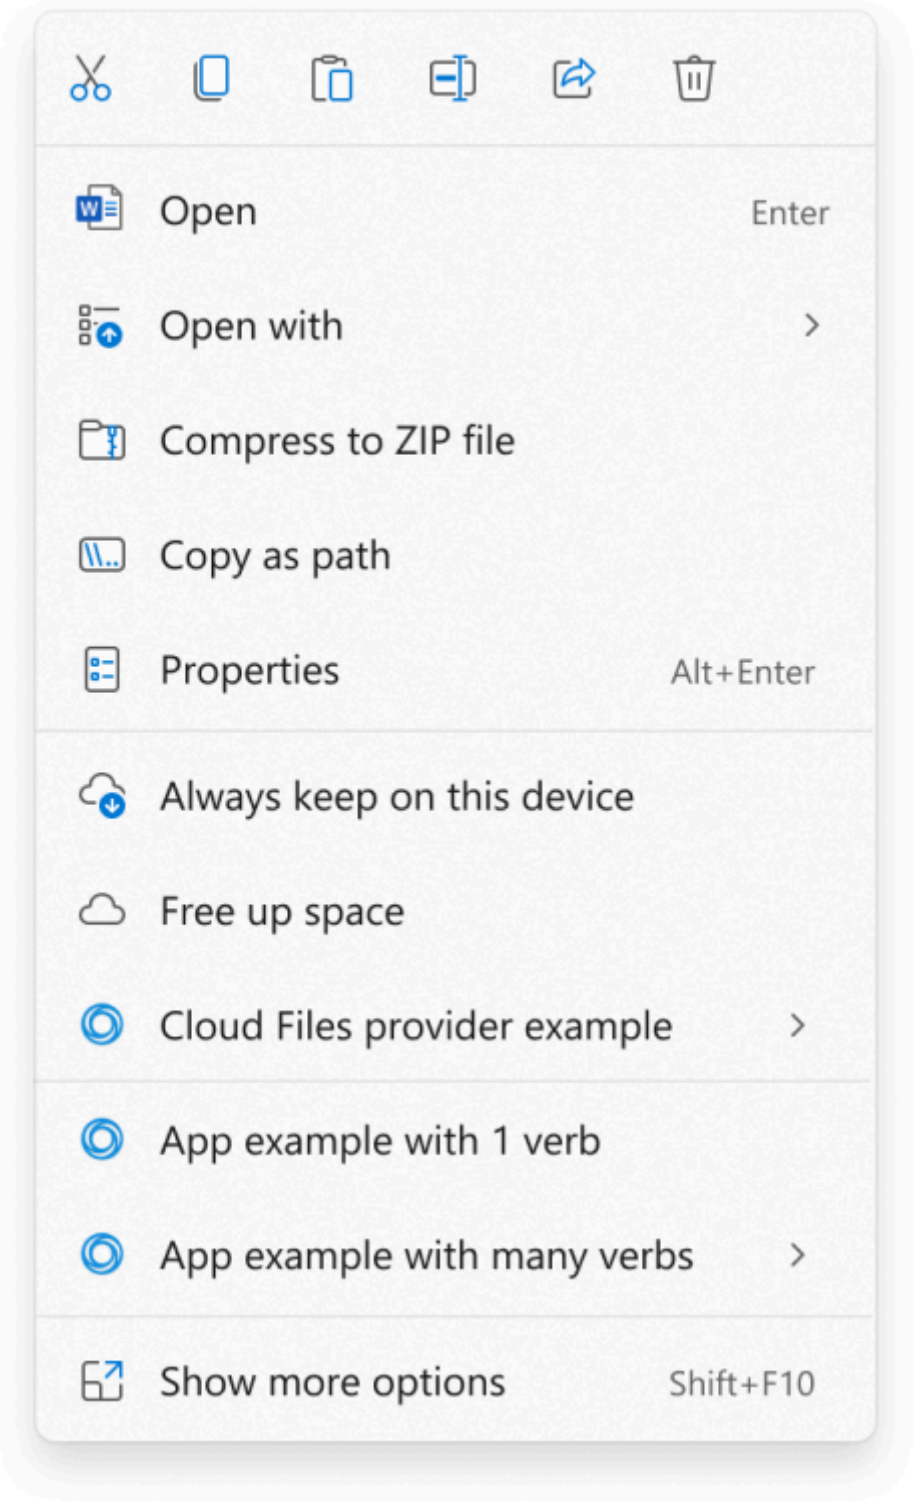
8. Optimize your app's context menu extensions and Share targets

Windows 11 refines the behavior of the contextual file operations in the right-click context menu of File Explorer and the Share dialog. If your app creates context menus or defines share targets, you may need to make some changes to ensure that these work well with Windows 11.

Context menus

For Windows 11, we improved the behavior of the context menu in File Explorer in several ways:

- Common commands, such as **Cut**, **Copy**, **Paste**, and **Delete**, have been moved to the top of the menu.
- **Open** and **Open with** are now grouped together.
- App extensions are grouped together below Shell verbs. Apps with more than one verb are grouped into a flyout with app attribution.
- Cloud files provider apps are placed next to the Shell commands to hydrate or dehydrate files.
- The older context menu from Windows 10 (along with lesser-used commands from the older context menu) is still available via the **Show more options** item at the bottom of the menu. **Shift** + **F10** or the keyboard menu key will also load the Windows 10 context menu.



If your app defines a context menu extension, the following requirements must be met for the extension to appear in the new Windows 11 context menu. Otherwise, your app's context menu extension will appear in the older context menu available via the **Show more options** item.

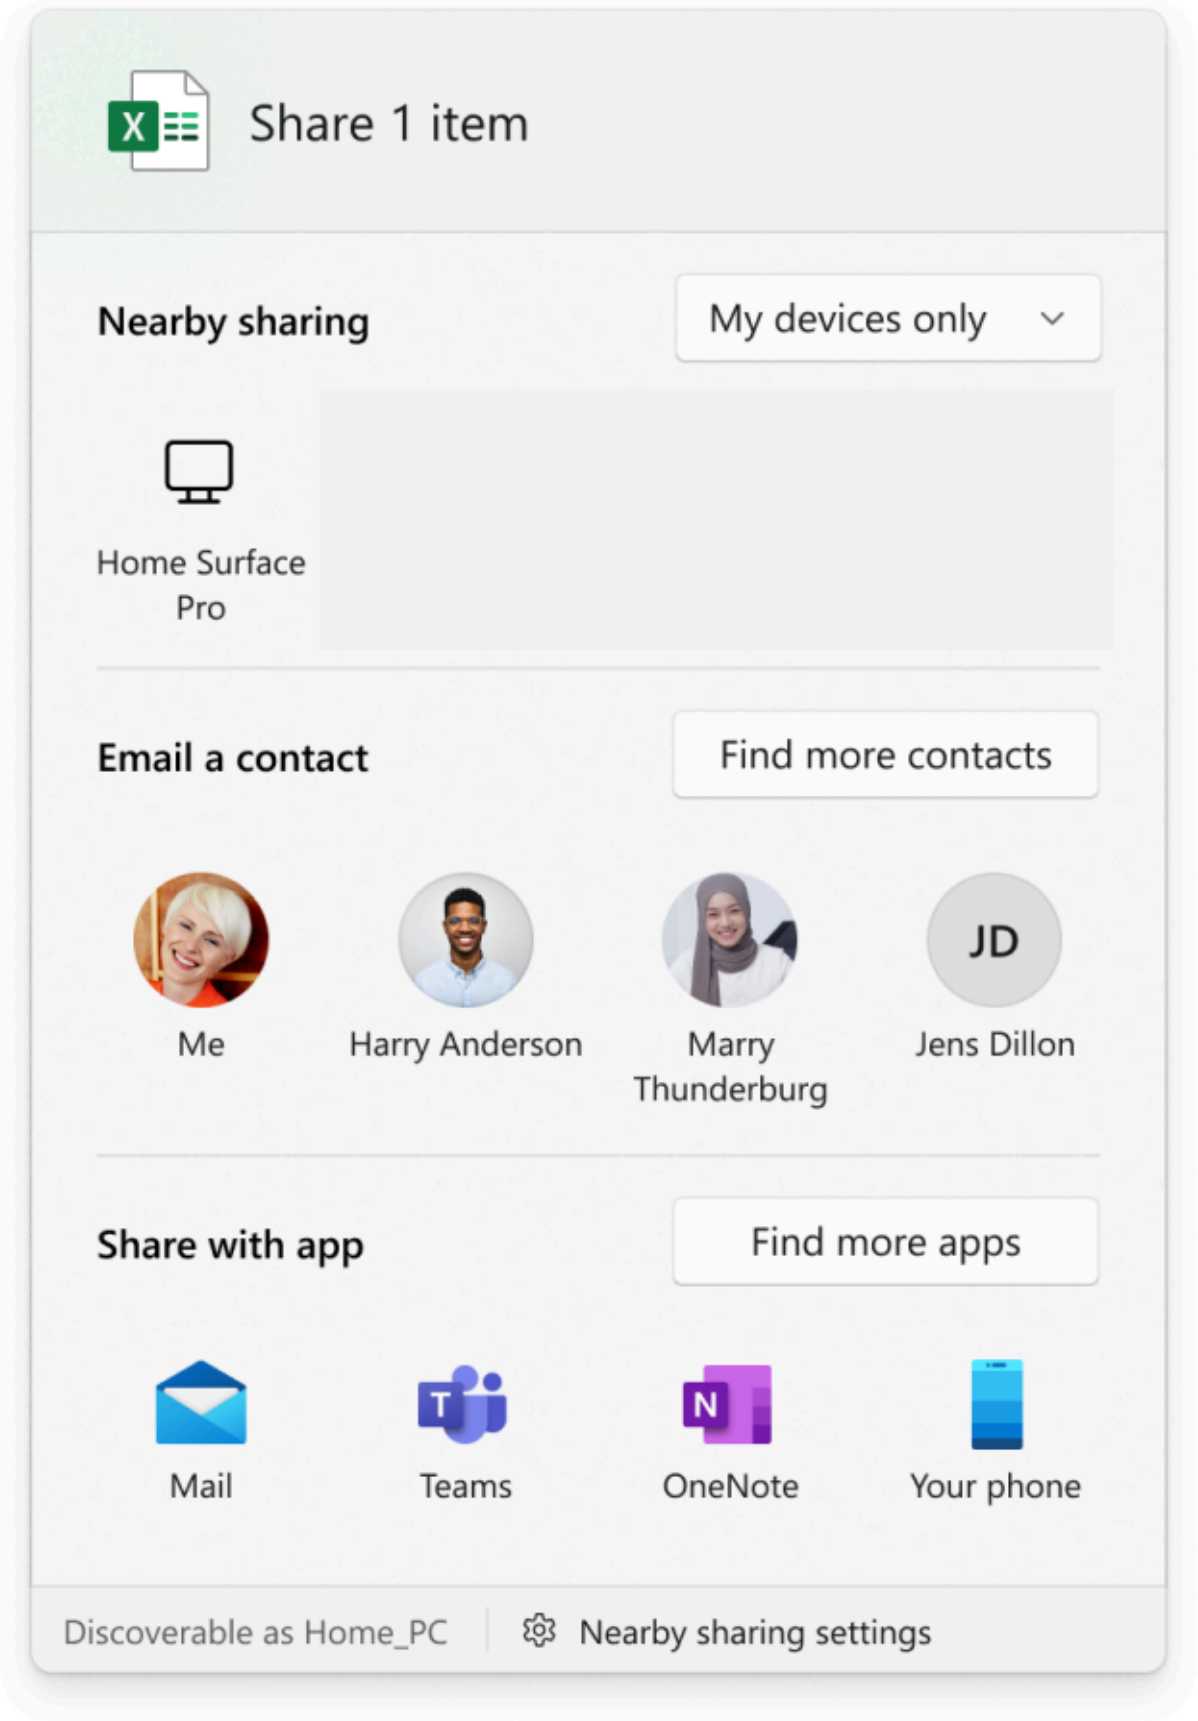
- Your context menu extension must be implemented by using the **IExplorerCommand** interface. Context menu extensions that implement **IContextMenu** will appear in the older context menu instead.

- Your app must be a *packaged app* so that it has package identity at runtime. See Features that require package identity for some options for packaging your app.

Share dialog

For Windows 11, we improved the behavior of the Share dialog in several ways.

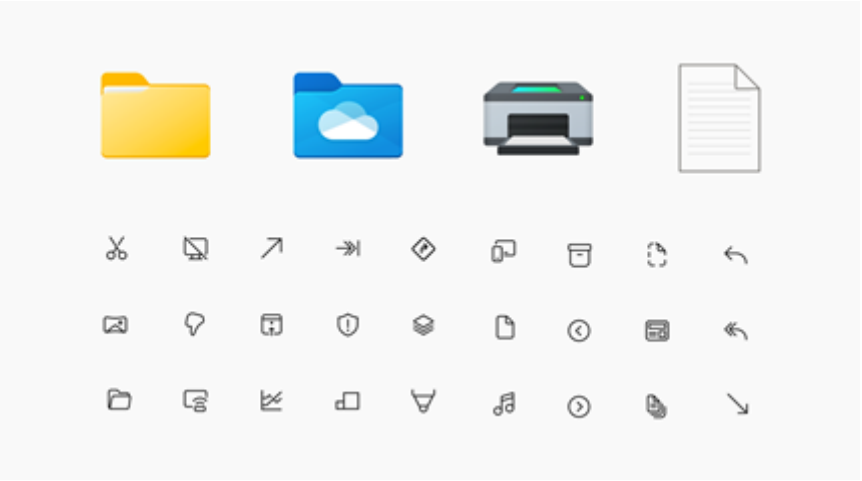
- Discoverability settings for nearby sharing are now at the top of the dialog and more settings are available at the bottom.
- All apps can now participate in the Share dialog as targets, including unpackaged desktop apps and PWAs that are installed through Microsoft Edge.
  - A previously unpackaged desktop app can participate as a target in the Share dialog if you package it with external location (see Grant package identity by packaging with external location). For sample code that demonstrates how to do that, see the SparsePackages sample app.
  - A PWA can participate in the Share dialog if it implements the Web Share Target API.



9. Use beautiful Iconography & Typography

We have updated icons and a new UI font called "Segoe UI Variable". We recommend all apps switch to using these new icons and font to be coherent on Windows 11. The new

font brings much softer geometry and makes the text much more legible.



- New icons called "Segoe Fluent Icons" are introduced for monoline icons. Controls in WinUI 2.6 and greater use the new icons and typography automatically.
- File type icons are updated. If your app is using icons in `imageres.dll` or `shell32.dll`, then icons will be updated automatically. Otherwise, a manual style update might be needed.
- App icons - Follow the latest design guidance for app icons used in places like launchers on Start and TaskBar.
- Animated icons - Lottie animation support was added to WinUI and we recommend using AnimatedIcon functionality to animate your icons in a meaningful way. Just as with other stylistic changes, you will need WinUI 2.6 or greater.
- Custom experiences written in XAML that specify `Segoe UI` in code, should instead specify `Segoe UI Variable`.

> **Note**
>
> When an app that uses the new font runs in Windows 10 or down-level, it will fallback to use the old font and degrade gracefully.

10. Make use of the innovative, secure features available in Windows

People run Windows across conventional devices as well as an increasingly diverse, modern range of devices. Devices today come not only with x86/x64-based, but also Arm-based, architectures; not only with mouse and keyboard but also touch screens, touchpads, and pens; with cameras, GPS, and sensors like gyroscopes; and with graphics and neural processing chipsets that enable not only amazing visuals but also hardware-

accelerated artificial intelligence (AI). Customers expect apps to take advantage of the hardware (that they have paid for!) and be cognizant of the device form factor to give them an appropriately optimized experience.

- Achieve AI powered productivity with Win ML - Introduction to Windows Machine Learning.
- Use AI models that power Windows Copilot Runtime on Copilot+ PCs and run locally - Windows Copilot Runtime overview.
- Utilize best practices for Notifications and content sharing - Notifications (Design basics).

Enhanced security features in Windows

Windows is built on a foundation of security and privacy, and Windows 11 is designed to be the most secure version of Windows yet, and we're committed to helping you build secure apps that take advantage of the latest security features in Windows.

- Protect your Windows apps and backend services with Windows Hello biometric sign-in - Windows Hello overview.
- Implement passkey sign-ins across online, enterprise, and government applications, and for payments - Intro to passkeys.
- Sign your apps with a digital certificate to ensure that Smart App Control can verify the integrity of your app - Introduction to code signing and Microsoft Trusted Root Program requirements.

11. Utilize the power of MSIX and Windows Store to package and distribute your application

Distribute your app wherever it makes sense for your business. Windows lets you distribute from your existing website, app management system, or the Windows Store.

- The Store lets you bring all of your Windows apps with no change, be it a native Windows app or a Progressive Web App (PWA). You can take your existing Windows app and list it on the store to drive app discovery. You choose whether you want to use the Store commerce and app distribution system, or use your existing systems. Either way, your app will be easily discoverable in the Windows Store.

  Learn more about Windows Store

- Make sure your app supports auto-updates, is efficient to install, and is manageable via MSIX.

  Keeping customers up to date with the latest version of your application is key to customer retention and appreciation. MSIX allows your app to seamlessly install and keep up to date without having to run a separate app update process. You get complete control over how this happens and on what schedule.

  What is MSIX?

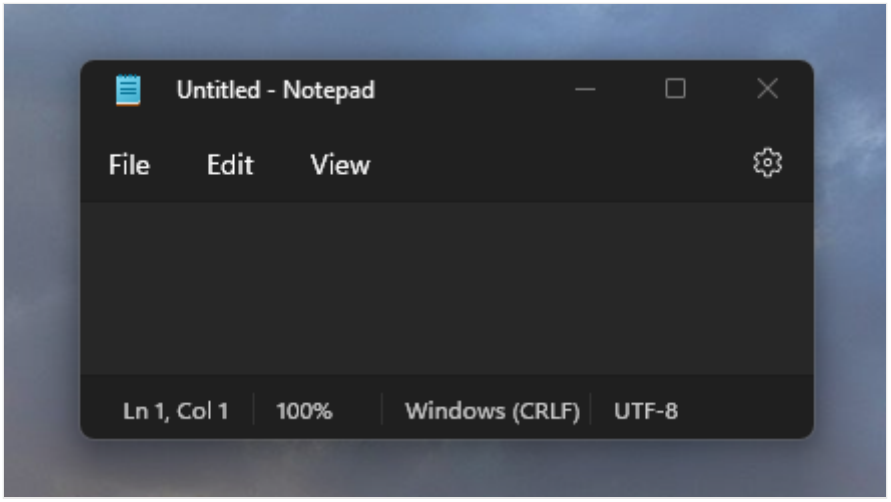
Apply rounded corners in desktop apps for Windows 11

Article • 08/21/2024

Rounded corners are the most immediately noticeable feature of Windows 11 Geometry. On Windows 11, the system automatically rounds top-level window corners for all inbox apps, including all UWP apps, and most other apps. However, some Win32 apps might not be rounded. This topic describes how to round your Win32 app's main window corners if the system does not round them automatically.

> **Note**
>
> By design, apps are not rounded when maximized, snapped, running in a Virtual Machine (VM), running on a Windows Virtual Desktop (WVD), or running as a Windows Defender Application Guard (WDAG) window.



Why isn't my app rounded?

If your app's main window doesn't receive automatic rounding, it's because you've customized your frame in a way that prevents it. Apps fall into three main categories from the perspective of the Desktop Window Manager (DWM):

1. Apps that are rounded by default.

   This includes apps that want a complete system-provided frame and caption-controls (min/max/close buttons), like Notepad. It also includes apps that provide enough information to the system so it can properly round them, such as setting

the WS_THICKFRAME and WS_CAPTION window styles or providing a 1-pixel non-client area border that the system can use to round the corners.

2. Apps that are not rounded by policy, but *can* be rounded.

   Apps in this category generally want to customize the majority of the window frame but still want the system-drawn border and shadow, such as Microsoft Office. If your app is not rounded by policy, it could be caused by one of the following things:

   - Lack of frame styles
   - Empty non-client area
   - Other customizations, such as extra non-child windows used for custom shadows

   Changing one of these things will break automatic rounding. Although we did try to round as many apps as possible with our system heuristics, there are some combinations of customizations that we can't predict so we provided a manual opt-in API for those cases. If you address these issues in your app or call the opt-in API, described in the following section, then it's possible for the system to round your app's window. Note, however, that the API is a hint to the system and does not guarantee rounding, depending on the customizations.

3. Apps that cannot ever be rounded, even if they call the opt-in API.

   These apps have no frame or borders, and typically have heavily customized UI. If your app does one of the following, it cannot be rounded:

   - Per-pixel alpha layering
   - Window regions

   For example, an app might use per-pixel alpha layering to draw transparent pixels around its main window to achieve a custom shadow effect, which makes the window no longer a rectangle and therefore the system cannot round it.

How to opt in to rounded corners

If your app is not rounded by policy, you can optionally use these APIs to let your app opt-in to rounded corners. You specify the corner rounding option you want for your app by passing a value of the **DWM_WINDOW_CORNER_PREFERENCE** enumeration (shown in the following table) to the **DwmSetWindowAttribute** function.

Expand table

Enum value	Description
DWMWCP_DEFAULT	Let the system decide whether or not to round window corners.
DWMWCP_DONOTROUND	Never round window corners.
DWMWCP_ROUND	Round the corners if appropriate.
DWMWCP_ROUNDSMALL	Round the corners if appropriate, with a small radius.

A pointer to the appropriate value from this enum is passed to the third parameter of **DwmSetWindowAttribute**. For the second parameter, which specifies which attribute you are setting, pass the **DWMWA_WINDOW_CORNER_PREFERENCE** value defined in the DWMWINDOWATTRIBUTE enumeration.

For C# apps

DwmSetWindowAttribute is a native Win32 API and is not exposed directly to .NET code. You'll need to use your language's implementation of P/Invoke to declare the function (C# code is given in the example below). All standard WinForms and WPF apps are rounded automatically, but if you customize your window frame or use a third party framework, you might need to opt-in to rounded corners. See the Examples section for further details.

Examples

The following examples show how you can call DwmSetWindowAttribute or DwmGetWindowAttribute to control your app's rounding experience if your app is not rounded by policy.

> ⓘ **Note**
>
> Error handling has been left out of these examples for brevity and clarity.

Example 1 - Rounding an app's main window in C# - WPF

This example shows how to call DwmSetWindowAttribute from C# by using the **[DllImport]** attribute. Note that this definition is specific to rounded corners; the DwmSetWindowAttribute function is designed to take different parameters depending on the flags provided, so this is not a general-purpose signature. The example also includes copies of the relevant enums from the dwmapi.h header file. Because the

Win32 API takes a pointer for the third parameter, make sure to use the *ref* keyword so you can pass the address of a variable when you call the function. You can do this in your MainWindow class in MainWindow.xaml.cs.

CSharp

```
using System.Runtime.InteropServices;
using System.Windows.Interop;

public partial class MainWindow : Window
{
    // The enum flag for DwmSetWindowAttribute's second parameter, which
tells the function what attribute to set.
    // Copied from dwmapi.h
    public enum DWMWINDOWATTRIBUTE
    {
        DWMWA_WINDOW_CORNER_PREFERENCE = 33
    }

    // The DWM_WINDOW_CORNER_PREFERENCE enum for DwmSetWindowAttribute's
third parameter, which tells the function
    // what value of the enum to set.
    // Copied from dwmapi.h
    public enum DWM_WINDOW_CORNER_PREFERENCE
    {
        DWMWCP_DEFAULT      = 0,
        DWMWCP_DONOTROUND   = 1,
        DWMWCP_ROUND        = 2,
        DWMWCP_ROUNDSMALL   = 3
    }

    // Import dwmapi.dll and define DwmSetWindowAttribute in C#
corresponding to the native function.
    [DllImport("dwmapi.dll", CharSet = CharSet.Unicode, PreserveSig =
false)]
    internal static extern void DwmSetWindowAttribute(IntPtr hwnd,
                                                       DWMWINDOWATTRIBUTE
attribute,
                                                       ref
DWM_WINDOW_CORNER_PREFERENCE pvAttribute,
                                                       uint cbAttribute);
    // ...
    // Various other definitions
    // ...
}
```

Next, in your MainWindow constructor, after the call to InitializeComponent, create a new instance of the WindowInteropHelper class to acquire a pointer to the underlying HWND (window handle). Make sure to use the EnsureHandle method to force the system to create an HWND for the window before it's shown, because normally the system only does so after exiting the constructor.

CSharp

```
public MainWindow()
{
    InitializeComponent();

    IntPtr hWnd = new WindowInteropHelper(GetWindow(this)).EnsureHandle();
    var attribute = DWMWINDOWATTRIBUTE.DWMWA_WINDOW_CORNER_PREFERENCE;
    var preference = DWM_WINDOW_CORNER_PREFERENCE.DWMWCP_ROUND;
    DwmSetWindowAttribute(hWnd, attribute, ref preference, sizeof(uint));

    // ...
    // Perform any other work necessary
    // ...
}
```

Example 2 - Rounding an app's main window in C# - WinForms

Like with WPF, for a WinForms app you'll first need to import dwmapi.dll and the DwmSetWindowAttribute function signature with P/Invoke. You can do this in your primary Form class.

Csharp

```
using System;
using System.Runtime.InteropServices;

public partial class Form1 : Form
{
    // The enum flag for DwmSetWindowAttribute's second parameter, which
tells the function what attribute to set.
    // Copied from dwmapi.h
    public enum DWMWINDOWATTRIBUTE
    {
        DWMWA_WINDOW_CORNER_PREFERENCE = 33
    }

    // The DWM_WINDOW_CORNER_PREFERENCE enum for DwmSetWindowAttribute's
third parameter, which tells the function
    // what value of the enum to set.
    // Copied from dwmapi.h
    public enum DWM_WINDOW_CORNER_PREFERENCE
    {
        DWMWCP_DEFAULT      = 0,
        DWMWCP_DONOTROUND   = 1,
        DWMWCP_ROUND        = 2,
        DWMWCP_ROUNDSMALL   = 3
    }
```

```
    // Import dwmapi.dll and define DwmSetWindowAttribute in C#
corresponding to the native function.
    [DllImport("dwmapi.dll", CharSet = CharSet.Unicode, PreserveSig =
false)]
    internal static extern void DwmSetWindowAttribute(IntPtr hwnd,
                                                       DWMWINDOWATTRIBUTE
attribute,
                                                       ref
DWM_WINDOW_CORNER_PREFERENCE pvAttribute,
                                                       uint cbAttribute);

    // ...
    // Various other definitions
    // ...
}
```

Calling DwmSetWindowAttribute is also the same as with a WPF app, but you don't have to use a helper class to get the HWND because it's simply a property of the Form. Call it from within your Form constructor, after the call to InitializeComponent.

CSharp

```
public Form1()
{
    InitializeComponent();

    var attribute = DWMWINDOWATTRIBUTE.DWMWA_WINDOW_CORNER_PREFERENCE;
    var preference = DWM_WINDOW_CORNER_PREFERENCE.DWMWCP_ROUND;
    DwmSetWindowAttribute(this.Handle, attribute, ref preference,
sizeof(uint));

    // ...
    // Perform any other work necessary
    // ...
}
```

Example 3 - Rounding an app's main window in C++

For a native C++ app, you can call DwmSetWindowAttribute in your message processing function after window creation to ask the system to round you.

C++

```
LRESULT ExampleWndProc(HWND hWnd, UINT message, WPARAM wParam, LPARAM
lParam)
{
    switch (message)
    {
    // ...
```

```
    // Handle various window messages...
    // ...

    case WM_CREATE:
        // ...
        // Perform app resource initialization after window creation
        // ...

        if(hWnd)
        {
            DWM_WINDOW_CORNER_PREFERENCE preference = DWMWCP_ROUND;
            DwmSetWindowAttribute(hWnd, DWMWA_WINDOW_CORNER_PREFERENCE,
&preference, sizeof(preference));
        }
        break;

    // ...
    // Handle various other window messages...
    // ...
    }

    return 0;
}
```

Example 4 – Rounding the corners of a menu with a small radius - C++

By default, menus are pop-up windows, which do not get rounded. If your app creates a custom menu and you want it to follow the rounding policy of other standard menus, you can call the API to let the system know that this window should be rounded, even though it doesn't appear to match the default rounding policy.

C++

```
HWND CreateCustomMenu()
{
    // Call an app-specific helper to make the window, using traditional
APIs.
    HWND hWnd = CreateMenuWindowHelper();

    if (hWnd)
    {
        // Make sure we round the window, using the small radius
        // because menus are auxiliary UI.
        DWM_WINDOW_CORNER_PREFERENCE preference = DWMWCP_ROUNDSMALL;
        DwmSetWindowAttribute(hWnd, DWMWA_WINDOW_CORNER_PREFERENCE,
&preference, sizeof(preference));
    }
```

```
    return hWnd;
}
```

Apply Mica in Win32 desktop apps for Windows 11

Article • 08/21/2024

Mica is an opaque material that incorporates the user's theme and desktop wallpaper to create a highly personalized appearance. As the user moves the window across the screen, the Mica material dynamically adapts to create a rich visualization using the wallpaper underneath the application. In addition, the material helps users focus on the current task by falling back to a neutral color when the app is inactive.

This article describes how to apply Mica as the base layer of your Win32 app, prioritizing application and visibility in the title bar area. For more information about app layering with Mica, see Mica material.

Prerequisites

To apply Mica to a Win32 app for Windows 11, you need to use the Windows App SDK. You'll need the following:

- Install the latest Windows App SDK Visual Studio Extension or Microsoft.WindowsAppSDK NuGet package. See Downloads for the Windows App SDK.
- For unpackaged apps, reference the Windows App SDK, install WinRT, and have a matching Windows App Runtime Redistributable (Microsoft.WindowsAppRuntime.Redist) installed. See Windows App SDK deployment guide for framework-dependent apps packaged with external location or unpackaged.

How to use Mica in Win32 Apps

To use mica in your app, you use the MicaController class. This class manages both the rendering of the system backdrop material as well as the handling of system policy for the mica material.

The MicaController reacts to the system Light and Dark themes by default. To override this behavior, you can pass the following properties to the MicaController:

- FallbackColor
- LuminosityOpacity
- TintColor

- TintOpacity

> **Tip**
>
> The code in this section is taken from the **Windows App SDK Win32 Mica sample on GitHub**. See the GitHub repo for the full code. These examples use **C++/WinRT**.

To enable Mica, you need a reference to the Windows App SDK, a Compositor, and a DispatcherQueue.

This example shows how to do the following to set up an unpackaged app:

- Initialize WinRT.
- Reference the WindowsAppSDK from an unpackaged app.
  - See Use the Windows App SDK runtime for apps packaged with external location or unpackaged for more info.
  - See `WindowsAppSDKBootstrapperContext` in Utilities.h for example code.
- Register the window class.
- Create the Mica dispatcher queue controller
- Initialize a WinRT compositor.

> From WinMain.cpp

C++

```
int __stdcall WinMain(_In_ HINSTANCE, _In_opt_ HINSTANCE,  _In_ PSTR, _In_
int)
{
    // Initialize WinRt Instance
    winrt::init_apartment();

    // Enable referencing the WindowsAppSDK from an unpackaged app.
    Utilities::WindowsAppSDKBootstrapperContext sdkContext;

    // Register Window class before making the window.
    MicaWindow::RegisterWindowClass();

    // Mica requires a compositor, which also requires a dispatcher queue.
    auto controller =
Utilities::CreateDispatcherQueueControllerForCurrentThread();
    auto compositor = winrt::Compositor();

    // Create your window...
    ...
}
```

> From MicaWindow.cpp

```
C++
```

```
void MicaWindow::RegisterWindowClass()
{
    auto instance = winrt::check_pointer(GetModuleHandleW(nullptr));
    WNDCLASSEX wcex = { sizeof(wcex) };
    wcex.style = CS_HREDRAW | CS_VREDRAW;
    wcex.lpfnWndProc = WndProc;
    wcex.hInstance = instance;
    wcex.hIcon = LoadIconW(instance, IDI_APPLICATION);
    wcex.hCursor = LoadCursorW(nullptr, IDC_ARROW);
    wcex.hbrBackground = (HBRUSH)(COLOR_WINDOW + 1);
    wcex.lpszClassName = ClassName.c_str();
    wcex.hIconSm = LoadIconW(wcex.hInstance, IDI_APPLICATION);
    winrt::check_bool(RegisterClassExW(&wcex)); // check if the window class
was registered successfully
}
```

The `winrt::init_apartment` method is multi-threaded by default. If your app requires a single-thread, like the WebView2 Sample, you can easily set the type.

```
C++
```

```
winrt::init_apartment(winrt::apartment_type::single_threaded);
```

Now you can use the `CreateWindowEx()` function to create a window. Then, you have to create a window target and set it as the root to specify which layer to apply Mica to. Finally, assert that Mica is supported by the window and target.

The Win32 Mica sample creates the DesktopWindow and MicaWindow classes to do this work. These classes define: `ClassName`, `windowTitle`, `m_target`, `m_micaController`, and `m_isMicaSupported`.

> From WinMain.cpp

```
C++
```

```
// Mica window is inherited from the MicaWindow class, which is an extension
of the DesktopWindow Class.
// Here, we initialize the main window and set the title.
   auto window = MicaWindow(compositor, L"Hello, Mica!");
```

> From MicaWindow.cpp

C++

```
// Create the main window and enable Mica.
MicaWindow::MicaWindow(const winrt::Compositor& compositor, const
std::wstring& windowTitle)
{
    auto instance = winrt::check_pointer(GetModuleHandleW(nullptr));
    WINRT_ASSERT(!m_window); // check that window is not initialized
    WINRT_VERIFY(
        // Window Properties
        CreateWindowExW(
            WS_EX_COMPOSITED,
            ClassName.c_str(), // declared in MicaWindow.h and defined above
            windowTitle.c_str(),
            WS_OVERLAPPEDWINDOW,
            CW_USEDEFAULT,
            CW_USEDEFAULT,
            800, 600,
            nullptr,
            nullptr,
            instance,
            this
        ));

    // Check that the window was created successfully.
    WINRT_ASSERT(m_window);

    ShowWindow(m_window, SW_SHOWDEFAULT);
    UpdateWindow(m_window);

    // The Mica controller needs to set a target with a root to recognize
the visual base layer.
    m_target = CreateWindowTarget(compositor);

    // Need to set a root before we can enable Mica.
    m_target.Root(compositor.CreateContainerVisual());

    m_micaController = winrt::MicaController();
    m_isMicaSupported =
m_micaController.SetTarget(winrt::Microsoft::UI::WindowId{
reinterpret_cast<uint64_t>(m_window) }, m_target);
}
```

How to use Mica in Win32 WebView2 apps

The fundamental principles of applying Mica are consistent across most Win32 applications. The process for WebView2 follows the basic steps from the Win32 instructions shown previously. However, in this case you will need to specify a single threaded process from WinRT's `init_apartment` feature.

> **Tip**
>
> The code in this section is taken from the **Windows App SDK WebView2 Mica sample on GitHub**. See the GitHub repo for the full code.

To get started, set up the required apartment, controller, compositor, target, and root. By default, the WinRT `init_apartment` function is multi-threaded, but WebView2 is inherently single-threaded. To set `init_apartment` as a single thread, pass the `winrt::apartment_type::single_threaded` parameter. In the Mica WebView2 Sample, we simplify the syntax by creating a separate class for web view functions, referenced in the following code.

> From Main.cpp

C++

```
int __stdcall WinMain(_In_ HINSTANCE, _In_opt_ HINSTANCE, _In_ PSTR, _In_
int)
{
    winrt::init_apartment(winrt::apartment_type::single_threaded);
    // Enable referencing the WindowsAppSDK from an unpackaged app.
    // Remember to have a matching Microsoft.WindowsAppRuntime.Redist
installed.
    // https://learn.microsoft.com/windows/apps/windows-app-sdk/deploy-
unpackaged-apps
    Utilities::WindowsAppSDKBootstrapperContext sdkContext;
    CompositionWindow::RegisterWindowClass();
    // A dispatcher queue is required to be able to create a compositor.
    auto controller =
Utilities::CreateDispatcherQueueControllerForCurrentThread();
    auto compositor = winrt::Compositor();
    auto window = WebView2Window(compositor, L"Hello, WebView2!");

    ...
}
```

For a full demonstration of the **WebView2Window class** and its integration with Mica, see the Windows App SDK WebView2 Mica sample on GitHub. Note how the CompositionWindow and WebView2Window classes handle messages, initialize the web view environment, and delete the window controller once the window is closed.

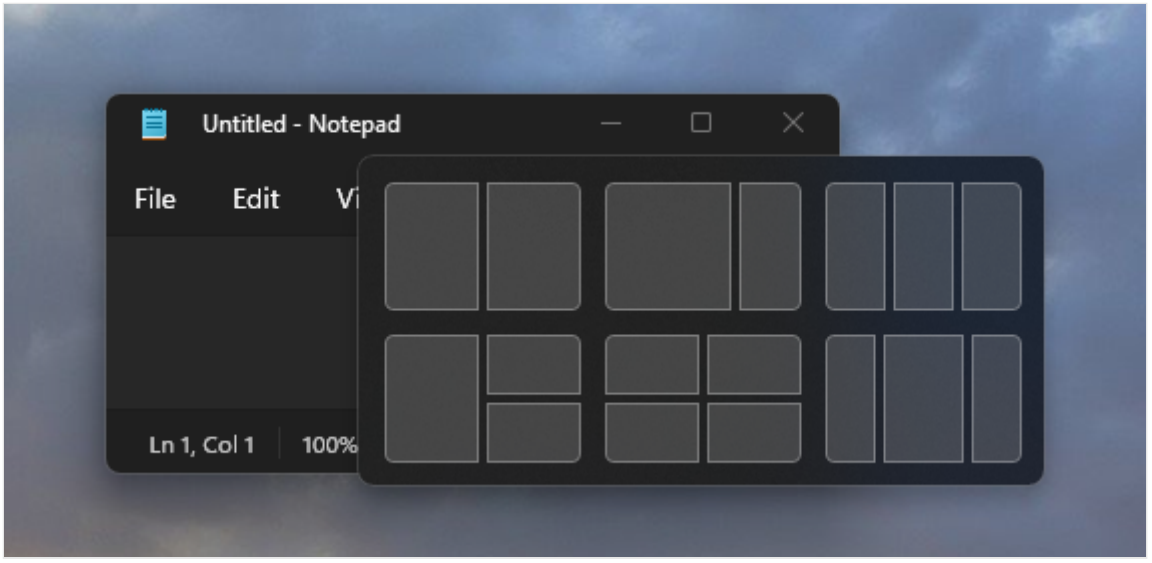
Support snap layouts for desktop apps on Windows 11

Article • 08/21/2024

Snap layouts are a new Windows 11 feature to help introduce users to the power of window snapping. Snap layouts are easily accessible by hovering the mouse over a window's maximize button or pressing Win + Z. After invoking the menu that shows the available layouts, users can click on a zone in a layout to snap a window to that particular zone and then use Snap Assist to finish building an entire layout of windows. Snap layouts are tailored to the current screen size and orientation, including support for three side-by-side windows on large landscape screens and top/bottom stacked windows on portrait screens.



If the app's window has the maximize caption button available, the system will automatically show snap layouts when a user hovers the mouse over the window's maximize button. Snap layouts will appear automatically for most apps, but some desktop apps may not show snap layouts. This topic describes how to make sure your app shows the menu with snap layouts if the system does not show it automatically.

Why doesn't my app show the snap layouts menu?

If your app's main window has the maximize caption button available but does not show snap layouts, it may be because you've customized your caption buttons or title bar in a way that prevents it.

How do I fix it?

If you have a custom title bar, then you can:

- Use the Windows App SDK windowing APIs (see Manage app windows) and have the platform draw and implement the caption buttons for you.
- For Win32 apps, make sure you are responding appropriately to WM_NCHITTEST (with a return value of `HTMAXBUTTON` for the maximize/restore button).

  C++

  ```
  LRESULT CALLBACK TestWndProc(HWND window, UINT msg, WPARAM wParam,
  LPARAM lParam)
  {
      switch (msg)
      {
            case WM_NCHITTEST:
          {
              // Get the point in screen coordinates.
              // GET_X_LPARAM and GET_Y_LPARAM are defined in windowsx.h
              POINT point = { GET_X_LPARAM(lParam), GET_Y_LPARAM(lParam)
  };
              // Map the point to client coordinates.
              ::MapWindowPoints(nullptr, window, &point, 1);
              // If the point is in your maximize button then return
  HTMAXBUTTON
              if (::PtInRect(&m_maximizeButtonRect, point))
              {
                  return HTMAXBUTTON;
              }
          }
          break;
      }
      return ::DefWindowProcW(window, msg, wParam, lParam);
  }
  ```

- If your app uses Electron, update to the v13 stable release of Electron to enable snap layouts.

What if my app's window shows snap layouts but isn't snapping properly?

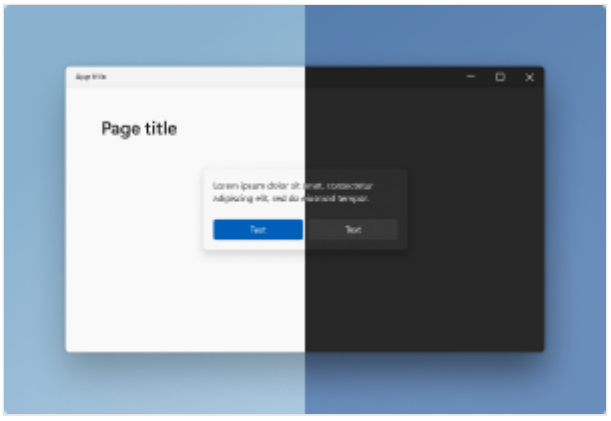
If your app can invoke the menu with snap layouts but isn't able to snap properly to the zone sizes, it's likely that your app's minimum window size is too large for the window to fit in the selected zone.

Your app should support a minimum width of at *most* 500 effective pixels (epx) to support snap layouts across the most common screen sizes. However, we recommend that you support an even smaller minimum width (330 epx or less) so that it's compatible with a larger set of devices and snap layouts.

Support Dark and Light themes in Win32 apps

Article • 08/21/2024

Windows supports *Light* and *Dark* themes as a personalization option in Windows settings. Windows uses Light mode by default, but users can choose Dark mode, which changes much of the UI to a dark color. Users might prefer this setting because it's easier on the eyes in lower-light environments, or they might simply prefer a darker interface in general. Also, darker UI colors can reduce the battery usage on some types of computer displays, such as OLED screens.



We are working hard to broaden support for Dark mode without breaking existing applications, and to that end we're providing technical guidance for updating a Win32 desktop Windows app to support both Light and Dark modes.

Dark mode vs. Light mode

The Color Mode in settings (which includes Light and Dark modes) is a setting that defines the overall *foreground* and *background* colors for the operating system and apps.

Expand table

Mode	Description	Example
Light	A light background with a contrasting dark foreground. In Light Mode, you will generally see black or dark text on white or light backgrounds.	
Mode	Description	Example
Dark	A dark background with a contrasting light foreground. In Dark mode, you will generally see white or light text on black or dark backgrounds.	
> **Note**
>
> The reason we use "*black or dark*" and "*white or light*" is because there are additional colors such as the Accent color that can tint various foreground and background colors. So you might in fact see light blue text on a dark blue background in some parts of the UI, and that would still be considered acceptable Dark mode UI.

Due to the wide diversity of UI in different apps, the color mode, and foreground and background colors are meant as more of a directional guideline than a hard rule:

- Foreground elements, highlights, and text should be closer to the foreground color than the background color.
- Large, solid background areas and text backgrounds should generally be closer to the background color than the foreground color.

In practice, this means that in Dark mode, most of the UI will be dark, and in Light mode most of the UI will be light. The concept of a background in Windows is the large area of colors in an app, or the page color. The concept of a foreground in Windows is the text color.

> **Tip**
>
> If you find it confusing that the *foreground* color is light in Dark mode and dark in Light mode, it may help to think of the foreground color as "the default text color".

Enable support for switching color modes

There are many approaches to implementing Dark mode support in an application. Some apps contain two sets of UIs (one with a light color and one with a dark color). Some Windows UI frameworks, such as WinUI 3, automatically detect a system's theme

and adjust the UI to follow the system theme. To fully support Dark mode, the entirety of an app's surface must follow the dark theme.

There are two main things you can do in your Win32 app to support both Light and Dark themes.

- **Know when Dark mode is enabled**

  Knowing when Dark mode is enabled in the system settings can help you know when to switch your app UI to a Dark mode-themed UI.

- **Enable a Dark mode title bar for Win32 applications**

  Not all Win32 applications support Dark mode, so Windows gives Win32 apps a light title bar by default. If you are prepared to support Dark mode, you can ask Windows to draw the dark title bar instead when Dark mode is enabled.

> **Note**
>
> This article provides examples of ways to detect system theme changes, and request a light or dark title bar for your Win32 application's window. It does not cover specifics of how to repaint and render your app UI using a Dark mode color set.

Know when Dark mode is enabled

The first step is to keep track of the color mode setting itself. This will let you adjust your application's painting and rendering code to use a Dark mode color set. Doing this requires the app to read the color setting at startup and to know when the color setting changes during an app session.

To do this in a Win32 application, use Windows::UI::Color and detect if a color can be classified as *light* or *dark*. To use `Windows::UI::Color`, you need to import (in `pch.h`) the `Windows.UI.ViewManagement` header from winrt.

```
C++
```

```
#include <winrt/Windows.UI.ViewManagement.h>
```

Also include that namespace in `main.cpp`.

```
C++
```

```
using namespace Windows::UI::ViewManagement;
```

In `main.cpp`, use this function to detect if a color can be classified as *light*.

C++

```
inline bool IsColorLight(Windows::UI::Color& clr)
{
    return (((5 * clr.G) + (2 * clr.R) + clr.B) > (8 * 128));
}
```

This function performs a quick calculation of the *perceived brightness* of a color, and takes into consideration ways that different channels in an RGB color value contribute to how bright it looks to the human eye. It uses all-integer math for speed on typical CPUs.

> **Note**
>
> This is not a model for real analysis of color brightness. It is good for quick calculations that require you to determine if a color can be classified as *light* or *dark*. Theme colors can often be light but not pure white, or dark but not pure black.

Now that you have a function to check whether a color is light, you can use that function to detect if Dark mode is enabled.

Dark mode is defined as a dark background with a contrasting light foreground. Since `IsColorLight` checks if a color is considered light, you can use that function to see if the foreground is light. If the foreground is light, then Dark mode is enabled.

To do this, you need to get the UI color type of the foreground from the system settings. Use this code in `main.cpp`.

C++

```
auto settings = UISettings();

auto foreground = settings.GetColorValue(UIColorType::Foreground);
```

UISettings gets all the settings of the UI including color. Call UISettings.GetColorValue(UIColorType::Foreground) to get the foreground color value from the UI settings.

Now you can run a check to see if the foreground is considered light (in `main.cpp`).

C++

```
bool isDarkMode = static_cast<bool>(IsColorLight(foreground));

wprintf(L"\nisDarkMode: %u\n", isDarkMode);
```

- If the foreground is light, then `isDarkMode` will evaluate to 1 (`true`) meaning Dark mode is enabled.
- If the foreground is dark, then `isDarkMode` will evaluate to 0 (`false`) meaning Dark mode is not enabled.

To automatically track when the Dark mode setting changes during an app session, you can wrap your checks like this.

C++

```
auto revoker = settings.ColorValuesChanged([settings](auto&&...)
{
    auto foregroundRevoker =
settings.GetColorValue(UIColorType::Foreground);
    bool isDarkModeRevoker = static_cast<bool>
(IsColorLight(foregroundRevoker));
    wprintf(L"isDarkModeRevoker: %d\n", isDarkModeRevoker);
});
```

Your full code should look like this.

C++

```
inline bool IsColorLight(Windows::UI::Color& clr)
{
    return (((5 * clr.G) + (2 * clr.R) + clr.B) > (8 * 128));
}

int main()
{
    init_apartment();

    auto settings = UISettings();
    auto foreground = settings.GetColorValue(UIColorType::Foreground);

    bool isDarkMode = static_cast<bool>(IsColorLight(foreground));
    wprintf(L"\nisDarkMode: %u\n", isDarkMode);

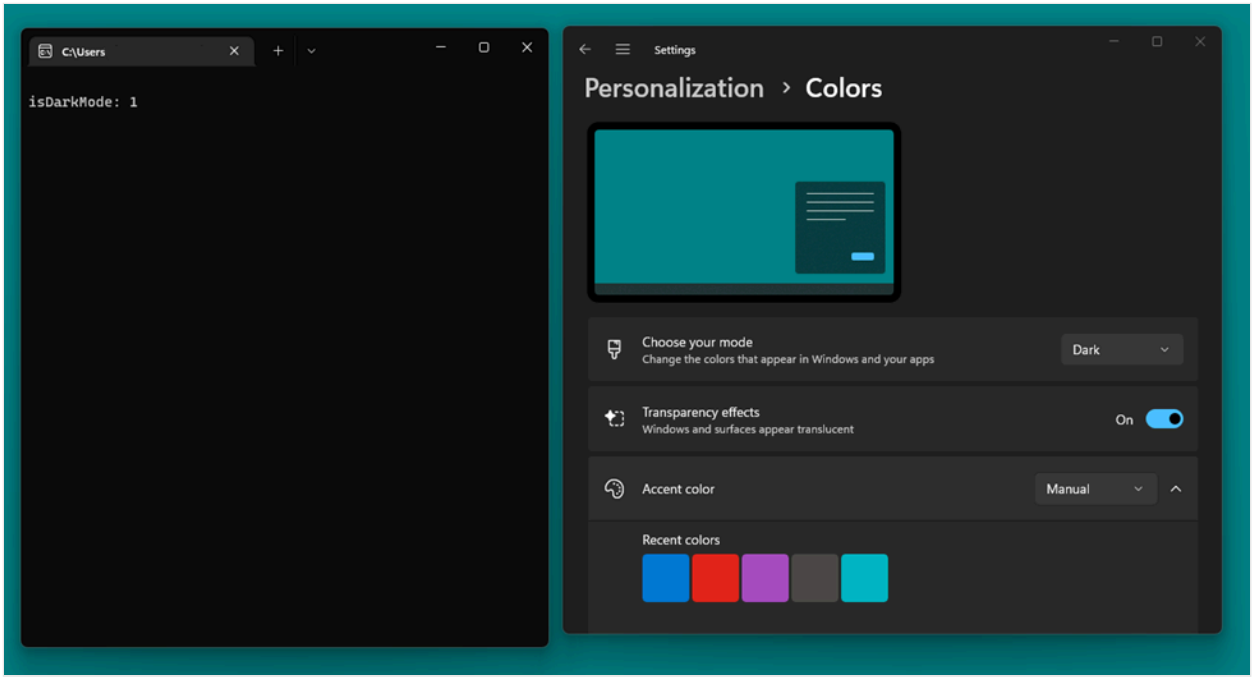
    auto revoker = settings.ColorValuesChanged([settings](auto&&...)
        {
```

```
            auto foregroundRevoker =
settings.GetColorValue(UIColorType::Foreground);
            bool isDarkModeRevoker = static_cast<bool>
(IsColorLight(foregroundRevoker));
            wprintf(L"isDarkModeRevoker: %d\n", isDarkModeRevoker);
        });

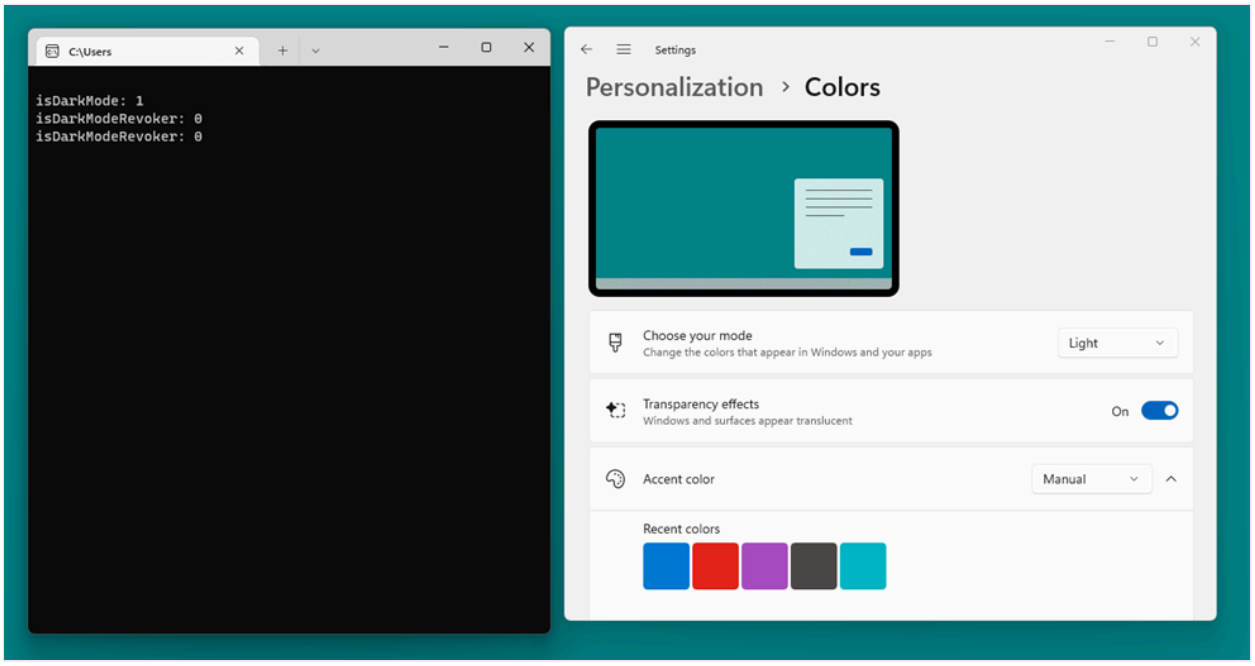
    static bool s_go = true;
    while (s_go)
    {
        Sleep(50);
    }
}
```

When this code is run:

If Dark mode is enabled, `isDarkMode` will evaluate to 1.



Changing the setting from Dark mode to Light mode will make `isDarkModeRevoker` evaluate to 0.



Enable a Dark mode title bar for Win32 applications

Windows doesn't know if an application can support Dark mode, so it assumes that it can't for backwards compatibility reasons. Some Windows development frameworks, such as Windows App SDK, support Dark mode natively and change certain UI elements without any additional code. Win32 apps often don't support Dark mode, so Windows gives Win32 apps a light title bar by default.

However, for any app that uses the standard Windows title bar, you can enable the dark version of the title bar when the system is in Dark mode. To enable the dark title bar, call a Desktop Windows Manager (DWM) function called DwmSetWindowAttribute on your top-level window, using the window attribute DWMWA_USE_IMMERSIVE_DARK_MODE. (DWM renders attributes for a window.)

The following examples assume you have a window with with a standard title bar, like the one created by this code.

C++

```
BOOL InitInstance(HINSTANCE hInstance, int nCmdShow)
{
   hInst = hInstance; // Store instance handle in our global variable

   HWND hWnd = CreateWindowW(szWindowClass, szTitle,
WS_OVERLAPPEDWINDOW,CW_USEDEFAULT, 0,
      CW_USEDEFAULT, 0, nullptr, nullptr, hInstance, nullptr);

   if (!hWnd)
```

```
   {
      return FALSE;
   }

   ShowWindow(hWnd, nCmdShow);
   UpdateWindow(hWnd);

   return TRUE;
}
```

First, you need to import the DWM API, like this.

C++

```
#include <dwmapi.h>
```

Then, define the `DWMWA_USE_IMMERSIVE_DARK_MODE` macros above your `InitInstance` function.

C++

```
#ifndef DWMWA_USE_IMMERSIVE_DARK_MODE
#define DWMWA_USE_IMMERSIVE_DARK_MODE 20
#endif

BOOL InitInstance(HINSTANCE hInstance, int nCmdShow)
{
…
```

Finally, you can use the DWM API to set the title bar to use a dark color. Here, you create a `BOOL` called `value` and set it to `TRUE`. This `BOOL` is used to trigger this Windows attribute setting. Then, you use `DwmSetWindowAttribute` to change the window attribute to use Dark mode colors.

C++

```
BOOL value = TRUE;
::DwmSetWindowAttribute(hWnd, DWMWA_USE_IMMERSIVE_DARK_MODE, &value,
sizeof(value));
```

Here's more explanation of what this call does.

The syntax block for DwmSetWindowAttribute looks like this.

C++

```
HRESULT DwmSetWindowAttribute(
       HWND    hwnd,
       DWORD   dwAttribute,
  [in] LPCVOID pvAttribute,
       DWORD   cbAttribute
);
```

After passing `hWnd` (the handle to the window you want to change) as your first parameter, you need to pass in `DWMWA_USE_IMMERSIVE_DARK_MODE` as the `dwAttribute` parameter. This is a constant in the DWM API that lets the Windows frame be drawn in Dark mode colors when the Dark mode system setting is enabled. If you switch to Light mode, you will have to change `DWMWA_USE_IMMERSIVE_DARK_MODE` from 20 to 0 for the title bar to be drawn in light mode colors.

The `pvAttribute` parameter points to a value of type `BOOL` (which is why you made the `BOOL` value earlier). You need `pvAttribute` to be `TRUE` to honor Dark mode for the window. If `pvAttribute` is `FALSE`, the window will use Light Mode.

Lastly, `cbAttribute` needs to have the size of the attribute being set in `pvAttribute`. To do easily do this, we pass in `sizeof(value)`.

Your code to draw a dark windows title bar should look like this.

C++

```
#ifndef DWMWA_USE_IMMERSIVE_DARK_MODE
#define DWMWA_USE_IMMERSIVE_DARK_MODE 20
#endif

BOOL InitInstance(HINSTANCE hInstance, int nCmdShow)
{
   hInst = hInstance; // Store instance handle in our global variable

   HWND hWnd = CreateWindowW(szWindowClass, szTitle, WS_OVERLAPPEDWINDOW,
      CW_USEDEFAULT, 0, CW_USEDEFAULT, 0, nullptr, nullptr, hInstance,
nullptr);

   BOOL value = TRUE;
   ::DwmSetWindowAttribute(hWnd, DWMWA_USE_IMMERSIVE_DARK_MODE, &value,
sizeof(value));

   if (!hWnd)
   {
      return FALSE;
   }

   ShowWindow(hWnd, nCmdShow);
```

```
    UpdateWindow(hWnd);

    return TRUE;
}
```

When this code is run, the app title bar should be dark:

Call Windows Runtime APIs in desktop apps

Article • 10/05/2022

This topic describes how to set up your desktop app projects to use Windows Runtime (WinRT) APIs provided by the Windows OS, and to add modern Windows 11 and Windows 10 experiences to your desktop apps.

Some Windows Runtime (WinRT) APIs are not supported in desktop apps. For more information, see Windows Runtime APIs not supported in desktop apps.

Modify a .NET project to use Windows Runtime APIs

There are several options for .NET projects:

- Starting in .NET 6, you can specify the Target Framework Moniker (TFM) in your project file to access WinRT APIs. This option is supported in projects that target Windows 10, version 1809 or later.
- For earlier versions of .NET, you can install the Microsoft.Windows.SDK.Contracts NuGet package to add all necessary references to your project. This option is supported in projects that target Windows 10, version 1803 or later.
- If your project multi-targets .NET 6 (or later) and earlier versions of .NET, then you can configure the project file to use both options.

.NET 6 and later: Use the Target Framework Moniker option

This option is supported only in projects that use .NET 6 (or later) and target Windows 10, version 1809 or a later OS release. By specifying a Windows OS version-specific TFM in the project file, a reference is added to the appropriate Windows SDK targeting package. For more background info about this scenario, see the blog post Calling Windows APIs in .NET.

1. With your project open in Visual Studio, right-click your project in **Solution Explorer** and choose **Edit Project File**. Your project file will look similar to this.

> **Note**

The example below shows an **OutputType** of *WinExe*, which specifies a Windows GUI executable (and prevents a console window from opening when the app runs). If your app doesn't have a GUI, then your **OutputType** will have a different value. You can call WinRT APIs from Windows GUI apps, console apps, and libraries. Also, your value for **TargetFramework** might not exactly match the example below.

XML

```xml
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <OutputType>WinExe</OutputType>
    <TargetFramework>net8.0</TargetFramework>
  </PropertyGroup>
</Project>
```

2. Leaving all other settings as they are, replace the value of the **TargetFramework** element with one of the following strings:

   - **net8.0-windows10.0.17763.0**: If your app targets Windows 10, version 1809.
   - **net8.0-windows10.0.18362.0**: If your app targets Windows 10, version 1903.
   - **net8.0-windows10.0.19041.0**: If your app targets Windows 10, version 2004.
   - **net8.0-windows10.0.22000.0**: If your app targets initial release of Windows 11.
   - **net8.0-windows10.0.22621.0**: If your app targets Windows 11, version 22H2.
   - **net8.0-windows10.0.26100.0**: If your app targets Windows 11, version 24H2.

   For example, the following element is for a project that targets Windows 10, version 2004.

   XML

   ```xml
   <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
   ```

   In later versions of .NET, you can replace the value with the relevant version, for example **net8.0-windows10.0.19041.0**.

3. Save your changes and close the project file.

WinRT APIs not supported in .NET 6 or later

In .NET 6 and later, there are several Windows Runtime (WinRT) APIs in the **Windows.UI** namespace that aren't supported. For the APIs listed below, equivalent versions of the

APIs exist in the WinUI (**Microsoft.UI**) namespace (for example, Microsoft.UI.Text). The following WinRT APIs are *not* supported on .NET 6 and later:

- Windows.UI.Colors class
- Windows.UI.ColorHelper class
- Windows.UI.Text (all classes in this namespace **except** for **Windows.UI.Text.FontStretch**, **Windows.UI.Text.FontStyle**, **Windows.UI.Text.FontWeight**, **Windows.UI.Text.UnderlineType**, and all classes under the **Windows.UI.Text.Core** namespace)
- Windows.UI.Xaml (all classes in this namespace)

Supporting multiple Windows OS versions

The Windows OS version-specific **TargetFramework** property determines the version of the Windows SDK that your app is compiled with. This property determines the set of accessible APIs at build time, and provides default values for both **TargetPlatformVersion** and **TargetPlatformMinVersion** (if not explicitly set). The **TargetPlatformVersion** property doesn't need to be explicitly defined in the project file, since it's automatically set by the **TargetFramework** OS version.

The **TargetPlatformMinVersion** can be overridden to be less than the **TargetPlatformVersion** (determined by the version in the **TargetFramework** property). This permits an app to run on earlier OS versions. For example, you can set the following in your project file to support your app downlevel to Windows 10, version 1809.

XML

```
<Project Sdk="Microsoft.NET.Sdk">
 <PropertyGroup>
   <OutputType>WinExe</OutputType>
   <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
   <TargetPlatformMinVersion>10.0.17763.0</TargetPlatformMinVersion>
 </PropertyGroup>
</Project>
```

Note that setting the **TargetPlatformMinVersion** to a version below the **TargetPlatformVersion** creates the potential for calling unavailable APIs. When calling WinRT APIs that are not available on all supported OS versions, we recommend guarding these calls with **ApiInformation** checks. For more information, see Version adaptive apps.

Earlier versions of .NET: Install the Microsoft.Windows.SDK.Contracts NuGet package

Use this option if your app uses .NET Core 3.x or .NET Framework. This option is supported in projects that target Windows 10, version 1803 or later.

1. Make sure package references are enabled:
   a. In Visual Studio, click **Tools -> NuGet Package Manager -> Package Manager Settings**.
   b. Make sure **PackageReference** is selected for **Default package management format**.

2. With your project open in Visual Studio, right-click your project in **Solution Explorer** and choose **Manage NuGet Packages**.

3. In the **NuGet Package Manager** window, select the **Browse** tab and search for `Microsoft.Windows.SDK.Contracts`.

4. After the `Microsoft.Windows.SDK.Contracts` package is found, in the right pane of the **NuGet Package Manager** window select the **Version** of the package you want to install based on the version of Windows 10 you want to target:

   - **10.0.19041.xxxx**: Choose this for Windows 10, version 2004.
   - **10.0.18362.xxxx**: Choose this for Windows 10, version 1903.
   - **10.0.17763.xxxx**: Choose this for Windows 10, version 1809.
   - **10.0.17134.xxxx**: Choose this for Windows 10, version 1803.

5. Click **Install**.

Configure projects that multi-target different versions of .NET

If your project multi-targets .NET 6 (or later) and earlier versions (including .NET Core 3.x and .NET Framework), then you can configure the project file to use the Target Framework Moniker (TFM) to automatically pull in the WinRT API references for .NET 6 (or later), and use the `Microsoft.Windows.SDK.Contracts` NuGet package for earlier versions.

1. With your project open in Visual Studio, right-click your project in **Solution Explorer** and choose **Edit Project File**. The following example demonstrates a project file for an app that uses .NET Core 3.1.

   > ⓘ **Note**
   >
   > The example below shows an **OutputType** of *WinExe*, which specifies a Windows GUI executable (and prevents a console window from opening when

the app runs). If your app doesn't have a GUI, then your **OutputType** will have a different value. You can call WinRT APIs from Windows GUI apps, console apps, and libraries. Also, your value for **TargetFramework** might not exactly match the example below.

XML

```
<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">
  <PropertyGroup>
    <OutputType>WinExe</OutputType>
    <TargetFramework>netcoreapp3.1</TargetFramework>
    <UseWindowsForms>true</UseWindowsForms>
  </PropertyGroup>
</Project>
```

2. Replace the **TargetFramework** element in the file with a **TargetFrameworks** element (note the plural). In this element, specify the Target Framework Monikers (TFMs) for all the versions of .NET you want to target, separated by semi-colons.

   - For .NET 6 or later, use one of the following Target Framework Monikers (TFMs):
     - **net6.0-windows10.0.17763.0**: If your app targets Windows 10, version 1809.
     - **net6.0-windows10.0.18362.0**: If your app targets Windows 10, version 1903.
     - **net6.0-windows10.0.19041.0**: If your app targets Windows 10, version 2004.
     - **net6.0-windows10.0.22000.0**: If your app targets initial release of Windows 11.
     - **net6.0-windows10.0.22621.0**: If your app targets Windows 11, version 22H2.
     - **net6.0-windows10.0.26100.0**: If your app targets Windows 11, version 24H2.
   - For .NET Core 3.x, use **netcoreapp3.0** or **netcoreapp3.1**.
   - For .NET Framework, use **net46**.

   The following example demonstrates how to multi-target .NET Core 3.1 and .NET 6 (for Windows 10, version 2004).

   XML

   ```
   <TargetFrameworks>netcoreapp3.1;net6.0-
   windows10.0.19041.0</TargetFrameworks>
   ```

3. After the **PropertyGroup** element, add a **PackageReference** element that includes a conditional statement that installs the `Microsoft.Windows.SDK.Contracts` NuGet package for any versions of .NET Core 3.x or .NET Framework that your app targets. The **PackageReference** element must be a child of an **ItemGroup** element. The following example demonstrates how to do this for .NET Core 3.1.

   XML

   ```
   <ItemGroup>
     <PackageReference Condition="'$(TargetFramework)' == 'netcoreapp3.1'"
                       Include="Microsoft.Windows.SDK.Contracts"
                       Version="10.0.19041.0" />
   </ItemGroup>
   ```

   When you're done, your project file should look similar to this.

   XML

   ```
   <Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">
     <PropertyGroup>
       <OutputType>WinExe</OutputType>
       <TargetFrameworks>netcoreapp3.1;net6.0-
   windows10.0.19041.0</TargetFrameworks>
       <UseWPF>true</UseWPF>
     </PropertyGroup>
     <ItemGroup>
       <PackageReference Condition="'$(TargetFramework)' ==
   'netcoreapp3.1'"
                         Include="Microsoft.Windows.SDK.Contracts"
                         Version="10.0.19041.0" />
     </ItemGroup>
   </Project>
   ```

4. Save your changes and close the project file.

Modify a C++ desktop (Win32) project to use Windows Runtime APIs

Use C++/WinRT to consume WinRT APIs. C++/WinRT is an entirely standard modern C++17 language projection for WinRT APIs, implemented as a header-file-based library, and designed to provide you with first-class access to the modern Windows API.

To configure your project for C++/WinRT:

- For new projects, you can install the C++/WinRT Visual Studio Extension (VSIX) and use one of the C++/WinRT project templates included in that extension.

- For existing projects, you can install the Microsoft.Windows.CppWinRT NuGet package in the project.

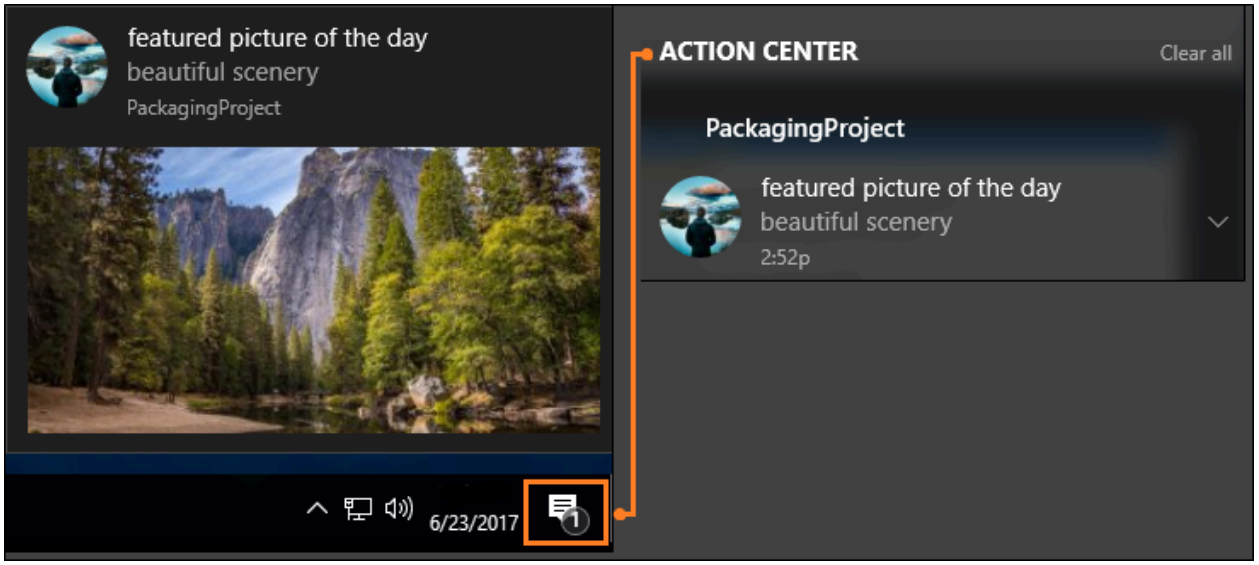
For more details about these options, see Visual Studio support for C++/WinRT, and the VSIX.

Add Windows 10 experiences

Now you're ready to add modern experiences that light up when users run your application on Windows 10. Use this design flow.

✅ **First, decide what experiences you want to add**

There's lots to choose from. For example, you can simplify your purchase order flow by using monetization APIs, or direct attention to your application when you have something interesting to share, such as a new picture that another user has posted.



Even if users ignore or dismiss your message, they can see it again in the action center, and then click on the message to open your app. This increases engagement with your application and has the added bonus of making your application appear deeply integrated with the operating system. We'll show you the code for that experience a bit later in this article.

Visit the UWP documentation for more ideas.

✅ **Decide whether to enhance or extend**

You'll often hear us use the terms *enhance* and *extend*, so we'll take a moment to explain exactly what each of these terms mean.

We use the term *enhance* to describe WinRT APIs that you can call directly from your desktop app whether or not it's a packaged app. When you've chosen a Windows 10 experience, identify the APIs that you need to create it, and then see if that API appears in this list. This is a list of APIs that you can call directly from your desktop app. If your API does not appear in this list, that's because the functionality associated with that API can run only within a UWP process. Often times, these include APIs that render UWP XAML such as a UWP map control or a Windows Hello security prompt.

> ⓘ **Note**
>
> Although APIs that render UWP XAML typically cannot be called directly from your desktop, you might be able to use alternative approaches. If you want to host UWP XAML controls or other custom visual experiences, you can use **XAML Islands** (starting in Windows 10, version 1903) and the **Visual layer** (starting in Windows 10, version 1803). These features can be used in packaged or unpackaged desktop apps.

If you have chosen to package your desktop app, then another option is to *extend* the application by adding a UWP project to your solution. The desktop project is still the entry point of your application, but the UWP project gives you access to all of the APIs that do not appear in this list. The desktop app can communicate with the UWP process by using a an app service and we have lots of guidance on how to set that up. If you want to add an experience that requires a UWP project, see Extend with UWP components.

✅ Reference API contracts

If you can call the API directly from your desktop app, open a browser and search for the reference topic for that API. Beneath the summary of the API, you'll find a table that describes the API contract for that API. Here's an example of that table:

Windows 10 requirements

Device family	Windows 10 (introduced v10.0.10240.0)
API contract	Windows.Foundation.UniversalApiContract (introduced v1)

If you have a .NET-based desktop app, add a reference to that API contract, and then set the **Copy Local** property of that file to **False**. If you have a C++-based project, add to your **Additional Include Directories**, a path to the folder that contains this contract.

✅ Call the APIs to add your experience

Here's the code that you'd use to show the notification window that we looked at earlier. These APIs appear in this list so you can add this code to your desktop app and run it right now.

C#

```
using Windows.Foundation;
using Windows.System;
using Windows.UI.Notifications;
using Windows.Data.Xml.Dom;
...

private void ShowToast()
{
    string title = "featured picture of the day";
    string content = "beautiful scenery";
    string image = "https://picsum.photos/360/180?image=104";
    string logo = "https://picsum.photos/64?image=883";

    string xmlString =
    $@"<toast><visual>
       <binding template='ToastGeneric'>
       <text>{title}</text>
       <text>{content}</text>
       <image src='{image}'/>
       <image src='{logo}' placement='appLogoOverride' hint-crop='circle'/>
       </binding>
      </visual></toast>";

    XmlDocument toastXml = new XmlDocument();
    toastXml.LoadXml(xmlString);

    ToastNotification toast = new ToastNotification(toastXml);

    ToastNotificationManager.CreateToastNotifier().Show(toast);
}
```

C++/WinRT

```
#include <sstream>
#include <winrt/Windows.Data.Xml.Dom.h>

ToastNotification(toastXml));
}
```

To learn more about notifications, see Adaptive and Interactive toast notifications.

Support Windows XP, Windows Vista, and Windows 7/8 install bases

You can modernize your application for Windows 10 without having to create a new branch and maintain separate code bases.

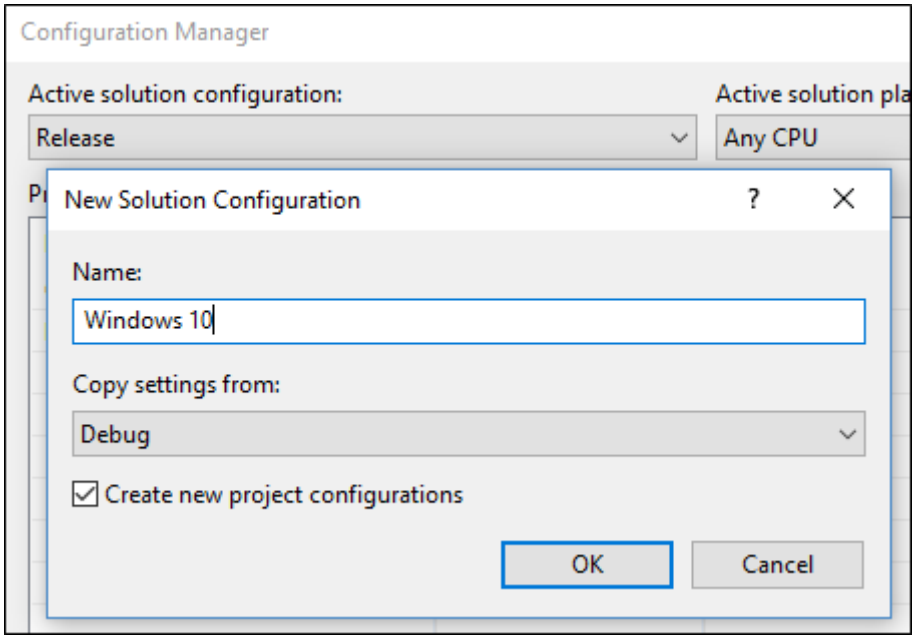
If you want to build separate binaries for Windows 10 users, use conditional compilation. If you'd prefer to build one set of binaries that you deploy to all Windows users, use runtime checks.

Let's take a quick look at each option.

Conditional compilation

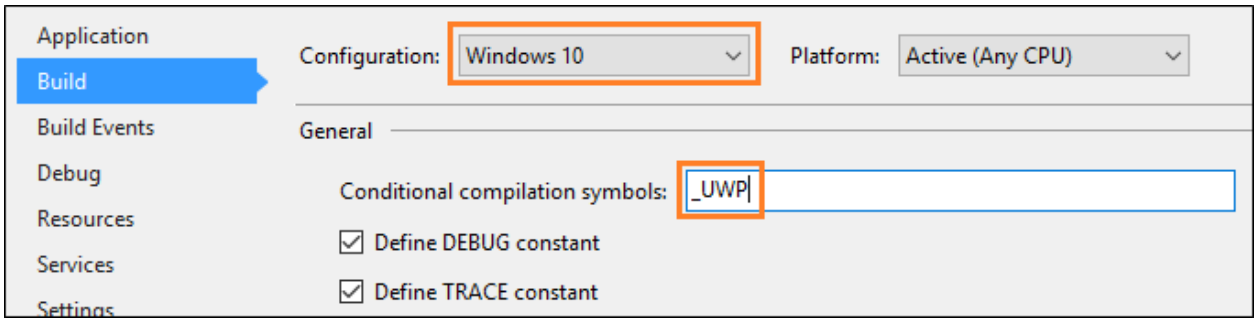
You can keep one code base and compile a set of binaries just for Windows 10 users.

First, add a new build configuration to your project.

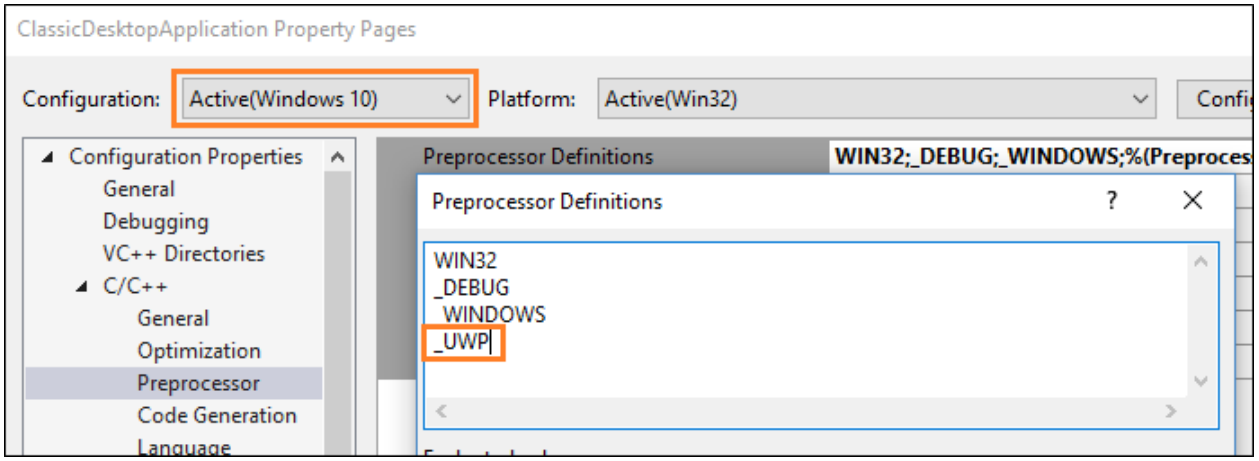


For that build configuration, create a constant that to identify code that calls WinRT APIs.

For .NET-based projects, the constant is called a **Conditional Compilation Constant**.



For C++-based projects, the constant is called a **Preprocessor Definition**.



Add that constant before any block of UWP code.

C#

```
[System.Diagnostics.Conditional("_UWP")]
private void ShowToast()
{
 ...
}
```

C++

```
#if _UWP
void UWP::ShowToast()
{
 ...
}
#endif
```

The compiler builds that code only if that constant is defined in your active build configuration.

Runtime checks

You can compile one set of binaries for all of your Windows users regardless of which version of Windows they run. Your application calls WinRT APIs only if the user is runs your application as a packaged application on Windows 10.

The easiest way to add runtime checks to your code is to install this Nuget package: Desktop Bridge Helpers and then use the `IsRunningAsUWP()` method to gate off all code that calls WinRT APIs. See this blog post for more details: Desktop Bridge - Identify the application's context.

Windows Runtime APIs not supported in desktop apps

Article • 02/27/2024

Although you can use most Windows Runtime (WinRT) APIs (see Windows UWP namespaces) in your C# or C++ desktop app, there are two main sets of WinRT APIs that aren't supported in desktop apps, or that have restrictions:

- APIs that have dependencies on user interface (UI) features that were designed for use only in a Universal Windows Platform (UWP) app.
- APIs that require package identity (see Features that require package identity). Such APIs are supported only in desktop apps that are packaged using MSIX.

This article provides details about both of those sets of WinRT APIs. Where available, this article suggests alternative APIs to achieve the same functionality as the APIs that are unsupported in desktop apps. Most of the alternative APIs are available in WinUI 3 or via WinRT COM interfaces that are available in the Windows SDK.

> **Note**
>
> Apps using .NET can make use of provided class implementations for some of the WinRT COM interfaces listed in this article. Those classes are easier to work with than using the WinRT COM interfaces directly. For more information about the available class implementations, see **Call interop APIs from a .NET app**. Note that those classes require the .NET 6 SDK or later.

This article will be updated as more workarounds and replacements are identified. If you encounter an issue with an API not listed here, please create an issue in the microsoft-ui-xaml repo with the API name and details about what you're trying to achieve by using it.

APIs that have dependencies on UWP-only UI features

Some WinRT APIs were designed specifically for UI scenarios in a UWP app. Those APIs do not behave properly in desktop apps due to threading model and other platform differences. Those APIs, and other WinRT APIs that have dependencies on them, aren't supported for use in desktop apps.

Core unsupported classes

These WinRT classes aren't supported in desktop apps:

Expand table

Class	Alternative APIs
ApplicationView	None
CoreApplicationView	Use the Window class provided by WinUI 3 instead.
CoreApplicationViewTitleBar	Instead of the ExtendViewIntoTitleBar property, use the Window.ExtendsContentIntoTitleBar property provided by WinUI 3.
CoreDispatcher	Use the Microsoft.UI.Xaml.Window.DispatcherQueue property provided by WinUI 3 instead. Note that the Windows.UI.Xaml.Window.Dispatcher and Windows.UI.Xaml.DependencyObject.Dispatcher properties return `null` in a desktop app.
CoreWindow	Also see the Classes that implement IInitializeWithWindow section below. Instead of the GetKeyState method, use the InputKeyboardSource.GetKeyStateForCurrentThread method provided by WinUI 3. Instead of the PointerCursor property, use the UIElement.ProtectedCursor property provided by WinUI 3. You'll need to have a subclass of UIElement to access that property.
UserActivity	Use the IUserActivitySourceHostInterop COM interface instead (in `useractivityinterop.h`).

For other WinRT APIs that aren't supported in desktop apps, see Unsupported members later in this topic.

Classes with an XxxForCurrentView method

Many WinRT classes have a static **GetForCurrentView** or **CreateForCurrentView** method, such as UIViewSettings.GetForCurrentView. Those **XxxForCurrentView** methods have an implicit dependency on the ApplicationView type, which isn't supported in desktop apps. Because **ApplicationView** isn't supported in desktop apps, none of the

XxxForCurrentView methods are supported either. Some unsupported **XxxForCurrentView** methods not only return `null`, but also throw exceptions.

> **Note**
>
> CoreInputView.GetForCurrentView *is* supported in desktop apps, and it *can* be used even without a CoreWindow. You can use that method to retrieve a CoreInputView object on any thread; and if that thread has a foreground window, then that object will produce events.

The following classes *are* supported in desktop apps; but to retrieve an instance of one in a desktop app, you use a mechanism that's different from the **GetForCurrentView** or **CreateForCurrentView** methods. For the classes below that have a COM interface listed as the alternative API, C# developers can also consume those WinRT COM interfaces (see Call interop APIs from a .NET app). The list might not be comprehensive.

Expand table

Class	Alternative APIs
AccountsSettingsPane	Use the IAccountsSettingsPaneInterop COM interface instead (in `accountssettingspaneinterop.h`).
CoreDragDropManager	Use the IDragDropManagerInterop COM interface instead (in `dragdropinterop.h`).
CoreTextServicesManager	This class is currently supported in desktop apps only in Windows Insider Preview builds.
DataTransferManager	Use the IDataTransferManagerInterop COM interface instead (in `shobjidl_core.h`).
DisplayInformation	To retrieve an instance of **DisplayInformation**, use the IDisplayInformationStaticsInterop interface. Alternatively, instead of the LogicalDpi property, you can use the XamlRoot.RasterizationScale property, and listen for changes via the XamlRoot.Changed event (the XamlRoot.RasterizationScale property is provided in WinUI 3). And, instead of the RawPixelsPerViewPixel property, you have the option to use the XamlRoot.RasterizationScale property provided by WinUI 3.
InputPane	Use the IInputPaneInterop COM interface instead (in `inputpaneinterop.h`).

Class	Alternative APIs
PlayToManager	Use the IPlayToManagerInterop COM interface instead (in `playtomanagerinterop.h`).
Print3DManager	Use the IPrinting3DManagerInterop COM interface instead (in `print3dmanagerinterop.h`).
PrintManager	Use the IPrintManagerInterop COM interface instead (in `printmanagerinterop.h`).
RadialController	Use the IRadialControllerInterop COM interface instead (in `radialcontrollerinterop.h`).
RadialControllerConfiguration	Use the IRadialControllerConfigurationInterop COM interface instead (in `radialcontrollerinterop.h`).
ResourceContext	See MRT to MRT Core migration.
ResourceLoader	See MRT to MRT Core migration.
SpatialInteractionManager	Use the ISpatialInteractionManagerInterop COM interface instead (in `spatialinteractionmanagerinterop.h`).
SystemMediaTransportControls	Use the ISystemMediaTransportControlsInterop COM interface instead (in `systemmediatransportcontrolsinterop.h`).
UserActivityRequestManager	Use the IUserActivityRequestManagerInterop COM interface instead (in `useractivityinterop.h`).
UIViewSettings	Use the IUIViewSettingsInterop COM interface instead (in `uiviewsettingsinterop.h`).

The following classes are *not* supported in desktop apps because the APIs don't provide an alternative to their **GetForCurrentView** or **CreateForCurrentView** method. The list might not be comprehensive.

Expand table

Class	Alternative APIs
AppCapture	None
BrightnessOverride	None
ConnectedAnimationService	None
CoreInputView	None
CoreWindowResizeManager	None

Class	Alternative APIs
DisplayEnhancementOverride	None
EdgeGesture	None
GazeInputSourcePreview	None
HdmiDisplayInformation	None
HolographicKeyboardPlacementOverridePreview	None
KeyboardDeliveryInterceptor	None
LockApplicationHost	None
MouseDevice	None
PointerVisualizationSettings	None
ProtectionPolicyManager	None
SearchPane	None
SettingsPane	None
SystemNavigationManager	None
SystemNavigationManagerPreview	None
WebAuthenticationBroker	None. for more details, see the WebAuthenticationBroker.AuthenticateAsync throws COMException GitHub issue.

Classes that implement IInitializeWithWindow

Certain pickers, popups, dialogs, and other Windows Runtime (WinRT) objects depend on a **CoreWindow**; typically, to display a UI. Even though **CoreWindow** isn't supported in desktop apps (see Core unsupported classes above), you can still use many of those WinRT classes in your desktop app by adding a little bit of interoperation code.

For more info (including a list of affected types), and code examples, see Display WinRT UI objects that depend on CoreWindow.

Unsupported members

This section lists (or describes, where a comprehensive list isn't possible) specific members of WinRT classes that aren't supported for use in desktop apps. Unless

otherwise noted, the rest of the classes apart from these members are supported in desktop apps.

Events

The following classes are supported in desktop apps, except for the specified event(s).

Expand table

Class	Unsupported events
UISettings	ColorValuesChanged
AccessibilitySettings	HighContrastChanged

Methods

The following classes are supported in desktop apps, except for the specified method(s).

Expand table

Class	Unsupported methods
DeviceInformationPairing	PairAsync

Methods that use the Request naming pattern

Most methods that follow the **Request** naming pattern—such as AppCapability.RequestAccessAsync and StoreContext.RequestPurchaseAsync—aren't supported in desktop apps. Internally, these methods use the Windows.UI.Popups class. That class requires that the thread have a CoreWindow object, which isn't supported in desktop apps.

The full list of methods that follow the **Request** naming pattern is very long, and this article doesn't provide a comprehensive list of those methods.

APIs that require package identity

The following WinRT classes require package identity (see Features that require package identity). These APIs are supported only in desktop apps that are packaged (that is, that have package identity at runtime). The list might not be comprehensive.

- Windows.ApplicationModel.DataTransfer.DataProviderHandler
- Windows.ApplicationModel.DataTransfer.DataRequest

Call interop APIs from a .NET app

Article • 10/24/2022

As a C# desktop application developer, in .NET you can make use of C# interop classes that represent several interoperability functions and Windows Runtime (WinRT) COM interoperability interfaces. These include C# classes representing IWindowNative, IInitializeWithWindow, the GetWindowIdFromWindow function, and many others.

This topic lists the available C# interop classes, and shows how to use them. The Background section at the end of the topic describes how interop interfaces were used in previous versions of .NET, and why the change was made.

Configure a .NET desktop project to use the C# interop classes

The C# interop classes listed in the next section (Available C# interop classes) are available in .NET either as part of the Windows App SDK, or else by using a particular Target Framework Moniker, as we'll see.

In a WinUI 3 C# desktop project

When you create a new WinUI 3 project in Visual Studio (see Create your first WinUI 3 project), your project is already configured, and you can start using all of the C# interop classes right away.

In other C# desktop project types (WPF or WinForms)

For other .NET desktop project types—such as Windows Presentation Foundation (WPF) or Windows Forms (WinForms)—you'll need to configure your project before you can access the C# interop classes. For the first set of classes listed below, you'll need to reference the Windows App SDK. For the second set, you'll need to configure a Target Framework Moniker that targets Windows 10, version 1809 or later, like this:

1. Open the project file for your C# .NET desktop project.
2. In the `.csproj` file, modify the **TargetFramework** element to target a specific .NET and Windows SDK version. For example, the following element is appropriate for a .NET 6 project that targets Windows 10, version 2004.

```
XML

<PropertyGroup>
  <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
```

```
</PropertyGroup>
```

For more information—including a list of other supported values—see Use the Target Framework Moniker option.

Available C# interop classes

> **Note**
>
> The classes below require the .NET 6 SDK or later.

Here are the available C# interop classes, mapped from their underlying interop function or WinRT COM interop interface. Each class listed implements the function/methods of its underlying interop API, and provides type-safe wrappers for parameters and return values. For example, **Windows.ApplicationModel.DataTransfer.DragDrop.Core.DragDropManagerInterop.GetForWindow** requires an **IntPtr** window handle (HWND) parameter, and returns a **CoreDragDropManager** object. All of the C# interop classes below and associated methods are static.

Available as part of the Windows App SDK

The **Microsoft.UI.Win32Interop** class implements the C# interop methods in the table below. For a code example, see Manage app windows.

Expand table

Interop function	C# interop method
GetDisplayIdFromMonitor	(**Microsoft.UI**) DisplayId **Win32Interop.GetDisplayIdFromMonitor**(IntPtr hmonitor)
GetIconFromIconId	(**Microsoft.UI**) IntPtr **Win32Interop.GetIconFromIconId**(IconId iconId)
GetIconIdFromIcon	(**Microsoft.UI**) IconId **Win32Interop.GetIconIdFromIcon**(IntPtr hicon)
GetMonitorFromDisplayId	(**Microsoft.UI**) IntPtr **Win32Interop.GetMonitorFromDisplayId**(DisplayId displayId)
GetWindowFromWindowId	(**Microsoft.UI**) IntPtr **Win32Interop.GetWindowFromWindowId**(WindowId windowId)
GetWindowIdFromWindow	(**Microsoft.UI**) WindowId **Win32Interop.GetWindowIdFromWindow**(IntPtr hwnd)

Available via Target Framework Moniker

Expand table

WinRT COM interop interface	C# interop class
IAccountsSettingsPaneInterop	(Windows.UI.ApplicationSettings) AccountsSettingsPaneInterop
IDisplayInformationStaticsInterop	Introduced with TFM `net6.0-windows10.0.22621.0` and .NET 6.0.7. (Windows.Graphics.Display) DisplayInformationInterop
IDragDropManagerInterop	(Windows.ApplicationModel.DataTransfer.DragDrop.Core) DragDropManagerInterop
IInitializeWithWindow	(WinRT.Interop) InitializeWithWindow
IInputPaneInterop	(Windows.UI.ViewManagement) InputPaneInterop
IPlayToManagerInterop	(Windows.Media.PlayTo) PlayToManagerInterop
IPrintManagerInterop	(Windows.Graphics.Printing) PrintManagerInterop
IRadialControllerConfigurationInterop	(Windows.UI.Input) RadialControllerConfigurationInterop
IRadialControllerIndependentInputSourceInterop	(Windows.UI.Input.Core) RadialControllerIndependentInputSourceInterop
IRadialControllerInterop	(Windows.UI.Input) RadialControllerInterop
ISpatialInteractionManagerInterop	(Windows.UI.Input.Spatial) SpatialInteractionManagerInterop
ISystemMediaTransportControlsInterop	(Windows.Media) SystemMediaTransportControlsInterop
IUIViewSettingsInterop	(Windows.UI.ViewManagement) UIViewSettingsInterop
IUserConsentVerifierInterop	(Windows.Security.Credentials.UI) UserConsentVerifierInterop
IWebAuthenticationCoreManagerInterop	(Windows.Security.Authentication.Web.Core) WebAuthenticationCoreManagerInterop
IWindowNative	WinUI 3 only (WinRT.Interop) WindowNative For alternatives for WPF and WinForms, see Retrieve a window handle (HWND).

Code example

This code example demonstrates how to use two of the C# interop classes in a WinUI 3 application (see Create your first WinUI 3 project). The example scenario is to display a **Windows.Storage.Pickers.FolderPicker**. But before displaying the picker in a desktop app, it's necessary to initialize it with the handle (HWND) of the owner window.

1. You can obtain a window handle (HWND) by using the **IWindowNative** WinRT COM interop interface. And (looking in the table in the previous section) that interface is represented by the **WinRT.Interop.WindowNative** C# interop class. Here, the `this` object is a reference to a **Microsoft.UI.Xaml.Window** object from the main window code-behind file.
2. To initialize a piece of UI with an owner window, you use the **IInitializeWithWindow** WinRT COM interop interface. And that interface is represented by the **WinRT.Interop.InitializeWithWindow** C# interop class.

C#

```
private async void myButton_Click(object sender, RoutedEventArgs e)
{
    // Create a folder picker.
    var folderPicker = new Windows.Storage.Pickers.FolderPicker();

    // 1. Retrieve the window handle (HWND) of the current WinUI 3 window.
    var hWnd = WinRT.Interop.WindowNative.GetWindowHandle(this);

    // 2. Initialize the folder picker with the window handle (HWND).
    WinRT.Interop.InitializeWithWindow.Initialize(folderPicker, hWnd);

    // Use the folder picker as usual.
    folderPicker.FileTypeFilter.Add("*");
    var folder = await folderPicker.PickSingleFolderAsync();
}
```

Also see Retrieve a window handle (HWND) and Display WinRT UI objects that depend on CoreWindow.

Background

Previous versions of the .NET Framework and .NET Core had built-in knowledge of WinRT. With those previous versions, you could define an interop interface directly in C# with the ComImport attribute, and then directly cast a projected class to that interop interface.

Since WinRT is a Windows-specific technology, to support the portability and efficiency goals of .NET, we lifted the WinRT projection support out of the C# compiler and .NET runtime, and moved it into the C#/WinRT toolkit (see Built-in support for WinRT is removed from .NET).

While the ComImport technique still works for **IUnknown**-based interop interfaces, it no longer works for the IInspectable-based interfaces that are used for interoperating with

WinRT.

So as a replacement, in .NET, you can make use of the C# interop classes described in this topic.

Troubleshooting and known issues

There are currently no known issues for the C# interop classes. To provide feedback, or to report other issues, add your feedback to an existing issue, or file a new issue on the WindowsAppSDK GitHub repo.

Use MSIX framework packages dynamically from your desktop app

Article • 03/03/2023

The Windows App SDK and the Windows 11 OS both enable your apps to reference and use MSIX framework packages dynamically at run time by using a feature called *dynamic dependencies*. This feature is intended to be used primarily by unpackaged desktop apps to use APIs and other content provided by MSIX framework packages.

The most common scenario for using the dynamic dependencies feature is to reference the Windows App SDK framework package in an unpackaged app. In some scenarios, you may want to use the dynamic dependencies feature to reference a different framework package from an unpackaged app, such as the framework package for WinUI 2 or the DirectX Runtime.

For an overview of the dynamic dependencies feature and guidance about using it in your apps, see the following articles.

Article	Description
MSIX framework packages and dynamic dependencies	Introduces important concepts related to MSIX framework packages and describes the purpose of dynamic dependencies feature. This article includes details about the package graph for framework package references and the servicing model for framework packages.
Use the Windows App SDK runtime for apps packaged with external location or unpackaged	Describes how to use dynamically take a dependency on the Windows App SDK framework package in an unpackaged app at run time. This scenario enables unpackaged apps to use Windows App SDK features.
Use the dynamic dependency API to reference MSIX packages at run time	Describes how to use the *dynamic dependency API* to dynamically take a dependency on different framework packages (other than the Windows App SDK framework package) in an unpackaged app at run time.

How packaged desktop apps run on Windows

For a deeper dive on what happens to files and registry entries when you create a Windows app package for your desktop application, see Understanding how packaged desktop apps run on Windows.

MSIX framework packages and dynamic dependencies

Article • 03/03/2023

This article introduces important concepts related to *MSIX framework packages*. The information in this article provides useful context to help you better understand the design and purpose of the *dynamic dependencies* feature in the Windows App SDK and in the Windows 11 OS. This feature enables your apps to reference and use MSIX framework packages at run time.

Framework packages and the package graph

MSIX is a package format that provides a modern packaging and deployment experience. It also provides a clean and trusted way to package redistributable libraries, content and components via *MSIX framework packages*. An MSIX framework package allows packaged apps to access components through a single shared source on the user's device, instead of bundling them into the app package. Common framework packages include the Windows App SDK (including WinUI3), WinUI2, VCLibs, and the DirectX Runtime.

Starting in Windows 8 and continuing through Windows 10 and Windows 11, every process has a *package graph* that provides the list of all the packages available to the app, including framework, resource, optional, and main packages. This graph allows the app to load DLLs, content, and run-time class declarations provided by a referenced package. Historically, this graph was fixed at process creation time, and there was no way to alter it at run time:

- For packaged apps, the graph was initialized based on the package dependencies declared in the PackageDependency element in the app's package manifest. When building a packaged app, this was typically done for you during the build process based on your project references and dependencies.
- For unpackaged apps, the package graph was empty, and couldn't be changed. Therefore, unpackaged apps were limited to standard DLL search order and couldn't access framework packages.

This static package graph restriction is lifted with the introduction of the dynamic dependencies support in both the Windows App SDK and in Windows 11. Developers can use dynamic dependencies to reference and use MSIX framework packages from their apps at run time. Dynamic dependencies removes the static package graph

restriction from apps, and developers can decide how they want to leverage framework packages.

Primary scenarios for dynamic dependencies

Although dynamic dependencies enables any app to add a package framework dependency at run time, this feature is primarily intended to be used by apps packaged with external location or unpackaged apps. Packaged apps can still continue to add static dependencies via the PackageDependency element in their package manifest.

- Most developers will use dynamic dependencies only to reference the Windows App SDK framework package in a packaged with external location or unpackaged app, so that the app can call APIs provided by the Windows App SDK runtime. For more information about this scenario, see Use the Windows App SDK runtime for apps packaged with external location or unpackaged.
- In some cases, developers may want to use dynamic dependencies to reference a different framework package (other than the Windows App SDK framework package) from an unpackaged app, such as the framework package for WinUI2 or the DirectX Runtime. For more information about this scenario, see Use the dynamic dependency API to reference MSIX packages at run time.

Servicing model for framework packages

The dynamic dependencies feature preserves the integrity of the servicing pipeline for the framework package that is being referenced and used dynamically at run time.

MSIX framework packages support servicing in a side-by-side model, meaning each version is installed in its own separate versioned folder. This allows applications in use to be able to stay up and running even when a newer app installs a newer version of the framework package. The OS has uninstall logic for when to delete older versions of a given framework package, based on the presence of *install-time references* and *run-time references* for the package.

- When an app is installed, it can create an *install-time reference* to a framework package. This reference informs the OS that the app has a dependency upon the specified framework package so that the OS won't uninstall the framework package while your app is installed.
- When an app needs to use APIs or content in a framework package, it can add a *run-time reference* to the framework package. This reference informs the OS that the framework package is in active use and to handle any version updates in a side-by-side manner. If a new version of the framework package is installed, but a

running app has an older version in use, the OS cannot remove the older version until all run-time references to the older version are removed.

For example, given this scenario:

- **App A** is running and using version 1.0.0.0 of a given framework package.
- **App B** is installed and has a dependency upon version 1.0.0.1 of the same framework package.

In this scenario, both versions of the framework package will be installed and in use by **App A** and **App B**. However, when **App A** is closed by the user and then restarted, it will pick up the newer version 1.0.0.1 of the framework package. At this point, the run-time reference requirement is no longer valid for version 1.0.0.0 of the framework package, and the OS can safely remove the 1.0.0.0 version. Later, when **App A** and **App B** are uninstalled by the user, then the install-time reference requirement is no longer valid and it is safe for the OS to remove the framework package entirely.

For packaged apps that use the PackageDependency element to specify static references to framework packages, the install-time references for framework packages are tracked by the OS when the app is installed or uninstalled. For run-time references that are managed by using the dynamic dependencies feature, the OS knows when a packaged app is running and will avoid removing its in-use framework packages when a newer one is available.

Use the dynamic dependency API to reference MSIX packages at run time

Article • 07/27/2023

The two implementations

There are two implementations of the *dynamic dependency API* that you can choose from, depending on your target platform and scenario:

- **The Windows App SDK's dynamic dependency API**. The Windows App SDK provides C and C++ functions (in msixdynamicdependency.h), and Windows Runtime (WinRT) types (in the **Microsoft.Windows.ApplicationModel.DynamicDependency** namespace) that implement the dynamic dependency API. You can use this implementation of the API on any version of Windows that supports the Windows App SDK.
- **Windows 11's dynamic dependency API**. Windows 11 also provides C and C++ functions that implement the dynamic dependency API (in appmodel.h). This implementation of the API can be used only by apps that target Windows 11, version 22H2 (10.0; Build 22621), and later.

Also see Differences between the two implementations.

> **Note**
>
> As you'll see in this topic, the Windows App SDK (C/C++) APIs have the same names as the Windows 11 (C/C++) APIs with an additional **Mdd** prefix. **Mdd** stands for *Microsoft Dynamic Dependencies*.

And there are different kinds of MSIX packages, including *framework*, *resource*, *optional*, and *main* packages. The dynamic dependency API enables unpackaged apps to reference and to use *framework* packages such as WinUI 2 and the DirectX Runtime. For more info about framework package dependencies, see MSIX framework packages and dynamic dependencies.

Specifically, the dynamic dependency API provides ways to manage the *install-time references* and *run-time references* for MSIX packages. For more info, see Servicing model for framework packages.

Use the dynamic dependency API

To use the dynamic dependency API in your unpackaged app to take a dependency on an MSIX package, follow this general pattern in your code:

1. Create an install-time reference

In your app's installer, or during the first run of your app, call one of the following functions or methods to specify a set of criteria for the MSIX package that you want to use. This informs the operating system (OS) that your app has a dependency on an MSIX package that meets the specified criteria. If one or more MSIX packages are installed that meet the criteria, then Windows ensures that at least one of them remains installed until the install-time reference is deleted.

- Windows 11 (C/C++): TryCreatePackageDependency
- Windows App SDK (C/C++): MddTryCreatePackageDependency
- Windows App SDK (WinRT): PackageDependency.Create

The criteria you specify include the package family name, minimum version, and architectures; but you can't indicate a specific MSIX package. When you add a run-time reference to the MSIX package, the API chooses the highest version that satisfies the specified criteria.

You must also specify a *lifetime artifact*, which can be the current process, a file, or a Windows Registry key that indicates to the system that the app is still available. If the specified artifact no longer exists, then the OS can assume that the dependency is no longer needed, and it can uninstall the MSIX package if no other apps have declared a dependency on it. That feature is useful for scenarios where an app neglects to remove the install-time pin when it is uninstalled.

This API returns a dependency ID that must be used in other calls to create run-time references, and to delete the install-time reference.

2. Add a run-time reference

When your app needs to use the MSIX package, call one of the following functions or methods to request access to the specified MSIX package, and add a run-time reference for it. Calling this API informs the OS that the MSIX package is in active use, and to handle any version updates in a side-by-side manner (effectively delay-uninstalling or otherwise servicing the older version until after the app is done using it). If successful, the app might activate classes and use content from the MSIX package.

- Windows 11 (C/C++): AddPackageDependency
- Windows App SDK (C/C++): MddAddPackageDependency
- Windows App SDK (WinRT): PackageDependency.Add

When you call this API, you must pass in the dependency ID that was returned when you created the install-time reference, and the desired rank to use for the MSIX package in the process's package graph. This API returns the full name of the MSIX package that was referenced, and a handle that is used to keep track of the active-use dependency. If there are multiple MSIX packages installed that meet the criteria that you specified when you created the install-time reference, then the API chooses the highest version that satisfies the criteria.

3. Remove the run-time reference

When your app is done using the MSIX package, call one of the following functions or methods to remove the run-time reference. Typically, your app will call this API during shutdown. This API informs the OS that it is safe to remove any unnecessary versions of the MSIX package.

- Windows 11 (C/C++): RemovePackageDependency
- Windows App SDK (C/C++): MddRemovePackageDependency
- Windows App SDK (WinRT): PackageDependencyContext.Remove

When you call this API, you must pass in the handle that was returned when you added the run-time reference.

4. Delete the install-time reference

When your app is uninstalled, call one of the following functions or methods to delete the install-time reference. This API informs the OS that it is safe to remove the MSIX package if no other apps have a dependency on it.

- Windows 11 (C/C++): DeletePackageDependency
- Windows App SDK (C/C++): MddDeletePackageDependency
- Windows App SDK (WinRT): PackageDependency.Delete

When you call this API, you must pass in the dependency ID that was returned when you created the install-time reference.

Differences between the two implementations

The need for a lifetime manager (Windows App SDK limitation)

When you use the Windows App SDK's dynamic dependency API to take a dependency on an MSIX package, the API requires help via another installed package and running process to inform Windows that the MSIX package is in use, and to block servicing the framework while it is being used. That component is called a *lifetime manager*.

For its framework package, the Windows App SDK provides a lifetime manager component called the Dynamic Dependency Lifetime Manager (DDLM). However, no other framework packages currently provide a similar lifetime manager component from Microsoft.

Windows 11's dynamic dependency API doesn't have this limitation.

Reference and use a main package (Windows App SDK limitation)

A dynamic dependency can always target a *framework* package. But only Windows 11's dynamic dependency API can reference and use *main* packages as well.

The main package must have correctly configured its app package manifest source file (the `Package.appxmanifest` file in Visual Studio). Specifically, the main package (the target, not the caller) needs to set `<uap15:DependencyTarget>true</>` (see uap15:DependencyTarget). So the purpose of `<uap15::DependencyTarget>` is to enable a dynamic dependency to target a *main* package. In other words, the main package has to opt in to allow itself to be used as a dynamic dependency (whereas framework packages always implicitly allow that).

Reference the Windows App SDK framework package (Windows App SDK limitation)

In an unpackaged app, you can't use the Windows App SDK's dynamic dependency API to reference the Windows App SDK framework package (like you *can* reference other MSIX packages with it). Instead, you need to use the bootstrapper API provided by the Windows App SDK. The bootstrapper API is a specialized form of the dynamic dependency API that's designed to take dependencies on the Windows App SDK framework package. For more info, see Use the Windows App SDK runtime for apps packaged with external location or unpackaged.

Windows 11's dynamic dependency API doesn't have this limitation.

Host WinRT XAML controls in desktop apps (XAML Islands)

Article • 08/21/2024

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

Starting in Windows 10, version 1903, you can host WinRT XAML controls in non-UWP desktop applications using a feature called *XAML Islands*. This feature enables you to enhance the look, feel, and functionality of your existing WPF, Windows Forms, and C++ desktop (Win32) applications with the latest Windows UI features that are only available via WinRT XAML controls. This means that you can use UWP features such as Windows Ink and controls that support the Fluent Design System in your existing WPF, Windows Forms, and C++ desktop applications.

You can host any WinRT XAML control that derives from Windows.UI.Xaml.UIElement, including:

- Most first-party WinRT XAML control provided by the Windows SDK or the WinUI 2 library (see exceptions).
- Any custom WinRT XAML control (for example, a user control that consists of several WinRT XAML controls that work together). You must have the source code for the custom control so you can compile it with your application.

Fundamentally, XAML Islands are created by using the *WinRT XAML hosting API*. This API consists of several Windows Runtime classes and COM interfaces that were introduced in the Windows 10, version 1903 SDK. We also provide a set of XAML Island .NET controls in the Windows Community Toolkit that use the WinRT XAML hosting API internally and provide a more convenient development experience for WPF and Windows Forms apps.

The way you use XAML Islands depends on your application type and the types of WinRT XAML controls you want to host.

> **Note**

If you have feedback about XAML Islands, create a new issue in the Microsoft.Toolkit.Win32 repo and leave your comments there.

Requirements

XAML Islands have these run time requirements:

- Windows 10, version 1903, or a later release.
- If your application is not packaged in an MSIX package for deployment, the computer must have the Visual C++ Runtime installed.

WPF and Windows Forms applications

> **Note**
>
> Using XAML Islands to host WinRT XAML controls in WPF and Windows Forms apps is currently supported only in apps that target .NET Core 3.x. XAML Islands are not yet supported in apps that target .NET, or in apps that any version of the .NET Framework.

We recommend that WPF and Windows Forms applications use the XAML Island .NET controls that are available in the Windows Community Toolkit. These controls provide an object model that mimics (or provides access to) the properties, methods, and events of the corresponding WinRT XAML controls. They also handle behavior such as keyboard navigation and layout changes.

There are two sets of XAML Island controls for WPF and Windows Forms applications: *wrapped controls* and *host controls*.

Wrapped controls

WPF and Windows Forms applications can use a selection of XAML Island controls that wrap the interface and functionality of a specific WinRT XAML control. You can add these controls directly to the design surface of your WPF or Windows Forms project and then use them like any other WPF or Windows Forms control in the designer.

The following wrapped WinRT XAML controls are currently available in the Windows Community Toolkit.

Expand table

Control	Minimum supported OS	Description
InkCanvas InkToolbar	Windows 10, version 1903	Provide a surface and related toolbars for Windows Ink-based user interaction in your Windows Forms or WPF desktop application.
MediaPlayerElement	Windows 10, version 1903	Embeds a view that streams and renders media content such as video in your Windows Forms or WPF desktop application.
MapControl	Windows 10, version 1903	Enables you to display a symbolic or photorealistic map in your Windows Forms or WPF desktop application.

For a walkthrough that demonstrates how to use the wrapped WinRT XAML controls, see Use XAML Islands to host a UWP XAML control in a C# WPF app.

Host controls

For custom controls and other scenarios beyond those covered by the available wrapped controls, WPF and Windows Forms applications can also use the WindowsXamlHost control that is available in the Windows Community Toolkit.

Expand table

Control	Minimum supported OS	Description
WindowsXamlHost	Windows 10, version 1903	Can host any WinRT XAML control that derives from Windows.UI.Xaml.UIElement, including any first-party WinRT XAML control provided by the Windows SDK as well as custom controls.

For walkthroughs that demonstrate how to use the **WindowsXamlHost** control, see Use XAML Islands to host a UWP XAML control in a C# WPF app and Host a custom WinRT XAML control in a WPF app using XAML Islands.

Configure your project to use the XAML Island .NET controls

The XAML Island .NET controls require Windows 10, version 1903, or a later version. To use these controls, install one of the NuGet packages listed below. These packages

provide everything you need to use the XAML Island wrapped controls and host controls, and they include other related NuGet packages that are also required.

Expand table

Type of control	NuGet package	Related articles
Wrapped controls	Version 6.0.0 or later of these packages: • WPF: Microsoft.Toolkit.Wpf.UI.Controls • Windows Forms: Microsoft.Toolkit.Forms.UI.Controls	Use XAML Islands to host a UWP XAML control in a C# WPF app
Host control	Version 6.0.0 or later of these packages: • WPF: Microsoft.Toolkit.Wpf.UI.XamlHost • Windows Forms: Microsoft.Toolkit.Forms.UI.XamlHost	Use XAML Islands to host a UWP XAML control in a C# WPF app Host a custom WinRT XAML control in a WPF app

Be aware of the following details:

- The host control packages are also included in the wrapped control packages. You can install the wrapped control packages if you want to use both sets of controls.
- If you're hosting a custom WinRT XAML control, you'll also need to perform some additional steps to reference the custom control. For more info, see Host a custom WinRT XAML control in a WPF app using XAML Islands.

Web view controls

The Windows Community Toolkit also provides the following .NET controls for hosting web content in WPF and Windows Forms applications. These controls are often used in similar desktop app modernization scenarios as the XAML Island controls, and they are maintained in the same Microsoft.Toolkit.Win32 repo as the XAML Island controls.

Expand table

Control	Minimum supported OS	Description
WebView	Windows 10, version 1803	Uses the Microsoft Edge rendering engine to show web content.

Control	Minimum supported OS	Description
WebViewCompatible	Windows 7	Provides a version of **WebView** that is compatible with more OS versions. This control uses the Microsoft Edge rendering engine to show web content on Windows 10 version 1803 and later, and the Internet Explorer rendering engine to show web content on earlier versions of Windows 10, Windows 8.x, and Windows 7.

To use these controls, install one of these NuGet packages:

- WPF: Microsoft.Toolkit.Wpf.UI.Controls.WebView
- Windows Forms: Microsoft.Toolkit.Forms.UI.Controls.WebView

C++ desktop (Win32) applications

The XAML Island .NET controls are not supported in C++ desktop applications. These applications must instead use the *WinRT XAML hosting API* provided by the Windows 10 SDK (version 1903 and later).

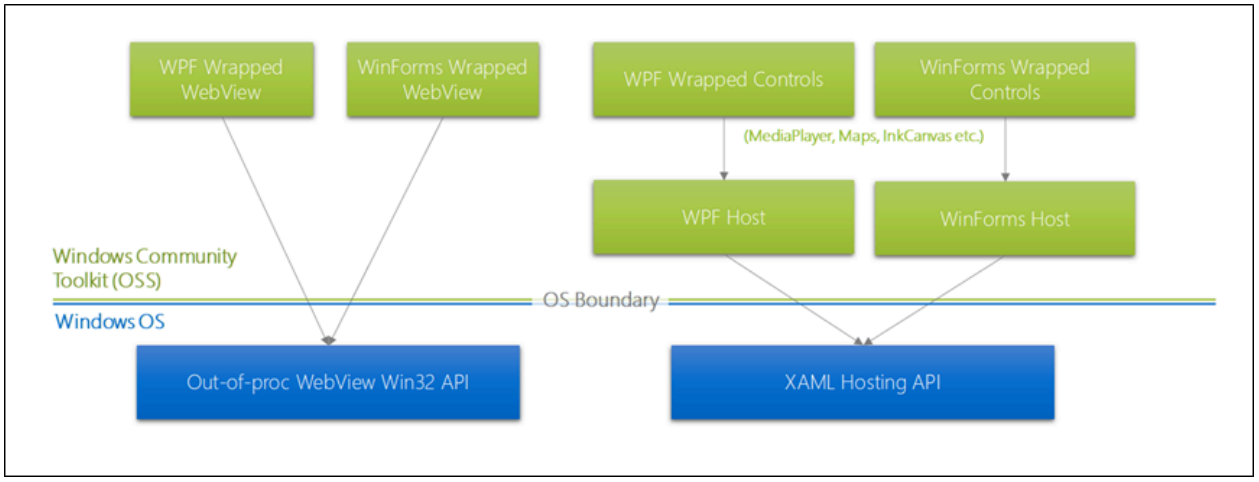
The WinRT XAML hosting API consists of several Windows Runtime classes and COM interfaces that your C++ desktop application can use to host any WinRT XAML control that derives from Windows.UI.Xaml.UIElement. You can host WinRT XAML controls in any UI element in your application that has an associated window handle (HWND). For more information about this API, see the following articles.

- Using the WinRT XAML hosting API in a C++ desktop app
- Host a standard WinRT XAML control in a C++ desktop app
- Host a custom WinRT XAML control in a C++ desktop app

> **Note**
>
> The wrapped controls and host controls in the Windows Community Toolkit use the WinRT XAML hosting API internally and implement all of the behavior you would otherwise need to handle yourself if you used the WinRT XAML hosting API directly, including keyboard navigation and layout changes. For WPF and Windows Forms applications, we strongly recommend that you use these controls instead of the WinRT XAML hosting API directly because they abstract away many of the implementation details of using the API.

Architecture of XAML Islands

Here's a quick look at how the different types of XAML Island controls are organized architecturally on top of the WinRT XAML hosting API.



The APIs that appear at the bottom of this diagram ship with the Windows SDK. The wrapped controls and host controls are available via NuGet packages in the Windows Community Toolkit.

Limitations and workarounds

The following sections discuss limitations and workarounds for certain UWP development scenarios in desktop apps that use XAML Islands.

Supported only with workarounds

✔ Hosting controls from the WinUI 2 Library in a XAML Island is supported conditionally in the current release of XAML Islands. If your desktop app uses an MSIX package for deployment, you can host WinUI controls from prerelease or release versions of the Microsoft.UI.Xaml NuGet package. If your desktop app is not packaged using MSIX, you can host WinUI controls only if you install a prerelease version of the Microsoft.UI.Xaml NuGet package, or if you use the Dynamic Dependencies API. Support for hosting controls from the WinUI 3.0 Library is coming in a later release.

✔ To access the root element of a tree of XAML content in a XAML Island and get related information about the context in which it is hosted, do not use the CoreWindow, ApplicationView, and Window classes. Instead, use the XamlRoot class. For more information, see this section.

✔ To support the Share contract from a WPF, Windows Forms, or C++ desktop (Win32) app, your app must use the IDataTransferManagerInterop interface to get the

DataTransferManager object to initiate the share operation for a specific window. For a sample that demonstrates how to use this interface in a WPF app, see the ShareSource sample.

✔ Using `x:Bind` with hosted controls in XAML Islands is not supported. You'll have to declare the data model in a .NET Standard library.

Not supported

🚫 Using XAML Islands in WPF and Windows Forms apps that target the .NET Framework. XAML Islands are supported only in apps that target .NET Core 3.x.

🚫 UWP XAML content in XAML Islands doesn't respond to Windows theme changes from dark to light or vice versa at run time. Content does respond to high contrast changes at run time.

🚫 Adding a Windows.UI.Xaml.WebView control. For WPF and WinForms apps, see these alternatives.

🚫 The MediaPlayer control and MediaPlayerElement host control are not supported in full screen mode.

🚫 Text input with the handwriting view. For more information about this feature, see this article.

🚫 Text controls that use `@Places` and `@People` content links. For more information about this feature, see this article.

🚫 XAML Islands do not support hosting a ContentDialog that contains a control that accepts text input, such as a TextBox, RichEditBox, or AutoSuggestBox. If you do this, the input control will not properly respond to key presses. To achieve similar functionality using a XAML Island, we recommend that you host a Popup that contains the input control.

🚫 XAML Islands do not currently support displaying SVG files in a hosted Windows.UI.Xaml.Controls.Image control or by using an Windows.UI.Xaml.Media.Imaging.SvgImageSource object. As a workaround, convert the image files you want to display to raster-based formats such as JPG or PNG.

Window host context for XAML Islands

When you host XAML Islands in a desktop app, you can have multiple trees of XAML content running on the same thread at the same time. To access the root element of a

tree of XAML content in a XAML Island and get related information about the context in which it is hosted, use the XamlRoot class. The CoreWindow, ApplicationView, and Window classes won't provide the correct information for XAML Islands. CoreWindow and Window objects do exist on the thread and are accessible to your app, but they won't return meaningful bounds or visibility (they are always invisible and have a size of 1x1). For more information, see Windowing hosts.

For example, to get the bounding rectangle of the window that contains a WinRT XAML control that is hosted in a XAML Island, use the XamlRoot.Size property of the control. Because every WinRT XAML control that can be hosted in a XAML Island derives from Windows.UI.Xaml.UIElement, you can use the XamlRoot property of the control to access the **XamlRoot** object.

```
C#

Size windowSize = myUWPControl.XamlRoot.Size;
```

Do not use the CoreWindows.Bounds property to get the bounding rectangle.

```
C#

// This will return incorrect information for a WinRT XAML control that is
hosted in a XAML Island.
Rect windowSize = CoreWindow.GetForCurrentThread().Bounds;
```

For a table of common windowing-related APIs that you should avoid in the context of XAML Islands and the recommended XamlRoot replacements, see the table in this section.

For a sample that demonstrates how to use this interface in a WPF app, see the ShareSource sample.

Additional resources

For more background information and tutorials about using XAML Islands, see the following articles and resources:

- Modernize a WPF app tutorial: This tutorial provides step-by-step instructions for using the wrapped controls and host controls in the Windows Community Toolkit to add WinRT XAML controls to an existing WPF line-of-business application. This tutorial includes the complete code for the WPF application as well as detailed instructions for each step in the process.

- XAML Islands code samples: This repo contains Windows Forms, WPF, and C++ desktop (Win32) samples that demonstrate how to use XAML Islands.
- XAML Islands v1 - Updates and Roadmap: This blog post discusses many common questions about XAML Islands and provides a detailed development roadmap.

Use XAML Islands to host a UWP XAML control in a C# WPF app

Article • 08/21/2024

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

This topic shows how to build a C# Windows Presentation Foundation (WPF) app (targeting .NET Core 3.1) that uses XAML Islands to host a Universal Windows Platform (UWP) XAML control (that is, a first-party control provided by the Windows SDK). We show how to do that in two ways:

- We show how to host UWP **InkCanvas** and **InkToolbar** controls by using wrapped controls (available in the Windows Community Toolkit). Wrapped controls wrap the interface and functionality of a small set of useful UWP XAML controls. You can add a wrapped control directly to the design surface of your WPF or Windows Forms project, and then use it in the designer like any other WPF or Windows Forms control.
- We also show how to host a UWP **CalendarView** control by using the **WindowsXamlHost** control (available in the Windows Community Toolkit). Because only a small set of UWP XAML controls are available as wrapped controls, you can use **WindowsXamlHost** to host any UWP XAML control.

The process for hosting a UWP XAML control in a WPF app is similar for a Windows Forms app.

> **Important**
>
> Using XAML Islands (wrapped controls or WindowsXamlHost) to host UWP XAML controls is supported only in apps that target .NET Core 3.x. XAML Islands are not supported in apps that target .NET, or in apps that target any version of the .NET Framework.

Recommended components

To host a UWP XAML control in a WPF or Windows Forms app, we recommend that you have the following components in your solution. This topic provides instructions for creating each of these components:

- **The project and source code for your WPF or Windows Forms app**.
- **A UWP project that defines a root Application class that derives from XamlApplication**. The Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class is available in the Windows Community Toolkit). We recommended that you define your **XamlApplication**-derived **Application** class a separate UWP app project that's part of your WPF or Windows Forms Visual Studio solution.

  > **Note**
  >
  > Making a **XamlApplication**-derived object available to your WPF or Windows Forms project isn't actually required in order to host a first-party UWP XAML control. But it *is* necessary in order to discover, load, and host custom UWP XAML controls. So—to support the full range of XAML Island scenarios—we recommend that you always define a **XamlApplication**-derived object in any solution in which you use XAML Islands.

  > **Note**
  >
  > Your solution can contain only one project that defines a **XamlApplication**-derived object. That one project must reference any other libraries and projects that host UWP XAML controls via XAML Islands.

Create a WPF project

You can follow these instructions to create a new WPF project, and configure it to host XAML Islands. If you have an existing WPF project, then you can adapt these steps and code examples for your project.

1. If you haven't done so already, then install the latest version of .NET Core 3.1.
2. In Visual Studio, create a new C# project from the **WPF Application** project template. Set the **Project name** to *MyWPFApp* so that you won't need to edit any of the steps or source code in this topic. Set the **Framework** to *.NET Core 3.1**, and click **Create**.

> **Important**
>
> Be sure not to use the **WPF App (.NET Framework)** project template.

Configure your WPF project

1. These steps enable package references:
   a. In Visual Studio, click **Tools** > **NuGet Package Manager** > **Package Manager Settings**.
   b. On the right, find the **Package Management** > **Default package management format** setting, and set it to **PackageReference**.

2. Use these steps to install the **Microsoft.Toolkit.Wpf.UI.Controls** NuGet Package:

   a. Right-click the *MyWPFApp* project node in **Solution Explorer**, and choose **Manage NuGet Packages...**.

   b. On the **Browse** tab, type or paste *Microsoft.Toolkit.Wpf.UI.Controls* into the search box. Select the latest stable version, and click **Install**. That package provides everything you need to use the wrapped UWP XAML controls for WPF (including **InkCanvas**, **InkToolbar**, and the **WindowsXamlHost** control).

   > **Note**
   >
   > For a Windows Forms app, reference the Microsoft.Toolkit.Forms.UI.Controls package instead.

3. Most XAML Islands scenarios aren't supported in projects that target **Any CPU**. So to target a specific architecture (such as **x86** or **x64**), do the following:
   a. Right-click the solution node (*not* the project node) in **Solution Explorer**, and choose **Properties**.
   b. Select **Configuration Properties** on the left.
   c. Click the **Configuration Manager...** button.
   d. Under **Active solution platform**, select **New**.
   e. In the **New Solution Platform** dialog, select **x64** or **x86**, and press **OK**.
   f. Close the open dialog boxes.

Define a XamlApplication class in a new UWP project

In this section we'll be adding a UWP project to the solution, and revising the default **App** class in that project to derive from the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class provided by the Windows Community Toolkit. That class supports the IXamlMetadataProvider interface, which enables your app to discover and load metadata for custom UWP XAML controls in assemblies in the current directory of your application at run time. That class also initializes the UWP XAML framework for the current thread.

1. In **Solution Explorer**, right-click the solution node, and select **Add** > **New Project...**.

2. Select the C# **Blank App (Universal Windows)** project template. Set the **Project name** to *MyUWPApp* so that you won't need to edit any of the steps or source code in this topic. Set the **Target version** and **Minimum version** to either **Windows 10, version 1903 (Build 18362)** or later.

   > **Note**
   >
   > Be sure not to create *MyUWPApp* in a subfolder of *MyWPFApp*. If you do that, then *MyWPFApp* will try to build the UWP XAML markup as if it were WPF XAML.

3. In *MyUWPApp*, install the Microsoft.Toolkit.Win32.UI.XamlApplication NuGet package (latest stable version). The process for installng a NuGet package was described in the previous section.

4. In *MyUWPApp*, open the `App.xaml` file, and replace its contents with the following XAML:

   XML

   ```
   <xaml:XamlApplication
       x:Class="MyUWPApp.App"
       xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
       xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
       xmlns:xaml="using:Microsoft.Toolkit.Win32.UI.XamlHost"
       xmlns:local="using:MyUWPApp">
   </xaml:XamlApplication>
   ```

5. Similarly, open `App.xaml.cs`, and replace its contents with the following code:

   C#

   ```
   namespace MyUWPApp
   {
   ```

```
    public sealed partial class App :
Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication
    {
        public App()
        {
            this.Initialize();
        }
    }
}
```

6. Delete the `MainPage.xaml` and `MainPage.xaml.cs` files.

7. Build the *MyUWPApp* project.

In MyWPFApp, add a reference to the MyUWPApp project

1. Specify the compatible framework version in *MyWPFApp*'s project file like this:

   a. In **Solution Explorer**, click the *MyWPFApp* project node to open the project file in the editor.

   b. Inside the first **PropertyGroup** element, add the following child element. Change the `19041` portion of the value as necessary to match the target and minimum OS build of the *MyWPFApp* project.

   XML

   ```
   <AssetTargetFallback>uap10.0.19041</AssetTargetFallback>
   ```

2. In **Solution Explorer**, right-click *MyWPFApp* > **Dependencies**, choose **Add Project Reference...**, and add a reference to the *MyUWPApp* project.

Instantiate the XamlApplication object in the entry point of MyWPFApp

Next, add code to the entry point of *MyWPFApp* to create an instance of the **App** class that you just defined in *MyUWPApp* (the class that derives from **XamlApplication**).

1. Right-click the *MyWPFApp* project node, select **Add** > **New Item...**, and then select **Class**. Set **Name** to *Program.cs*, and click **Add**.

2. Replace the contents of `Program.cs` with the following XAML (and then save the file and build the *MyWPFApp* project):

```
C#

namespace MyWPFApp
{
    public class Program
    {
        [System.STAThreadAttribute()]
        public static void Main()
        {
            using (new MyUWPApp.App())
            {
                var app = new MyWPFApp.App();
                app.InitializeComponent();
                app.Run();
            }
        }
    }
}
```

3. Right-click the *MyWPFApp* project node, and choose **Properties**.

4. In **Application** > **General**, click the **Startup object** drop-down, and choose *MyWPFApp.Program* (which is the fully-qualified name of the **Program** class that you just added). If you don't see it, then try closing and reopening Visual Studio.

   > **Note**
   >
   > By default, a WPF project defines a **Main** entry point function in a generated code file that isn't intended to be modified. The step above changes the entry point for your project to the **Main** method of the new **Program** class, which enables you to add code that runs as early in the startup process of the app as possible.

5. Save your changes to the project properties.

Use wrapped controls to host an InkCanvas and InkToolbar

Now that you've configured your project to use UWP XAML Islands, you're ready to add the InkCanvas and InkToolbar wrapped UWP XAML controls to the app.

1. In *MyWPFApp*, open the `MainWindow.xaml` file.

2. In the **Window** element near the top of the XAML file, add the following attribute. This attribute references the XAML namespace for the **InkCanvas** and **InkToolbar** wrapped UWP XAML controls, and maps it to the **controls** XML namespace.

```
XML

xmlns:controls="clr-
namespace:Microsoft.Toolkit.Wpf.UI.Controls;assembly=Microsoft.Toolkit.
Wpf.UI.Controls"
```

3. Still in `MainWindow.xaml`, edit the existing **Grid** element so that it looks like the XAML below. This XAML adds to the **Grid** an **InkCanvas** and an **InkToolbar** control (prefixed by the **controls** XML namespace that you defined in the previous step).

```
XML

<Grid Margin="10,50,10,10">
    <Grid.RowDefinitions>
        <RowDefinition Height="Auto"/>
        <RowDefinition Height="Auto"/>
    </Grid.RowDefinitions>
    <controls:InkToolbar x:Name="myInkToolbar" TargetInkCanvas="
{x:Reference myInkCanvas}" Grid.Row="0" Width="300"
        Height="50" Margin="10,10,10,10" HorizontalAlignment="Left"
VerticalAlignment="Top" />
    <controls:InkCanvas x:Name="myInkCanvas" Grid.Row="1"
HorizontalAlignment="Left" Width="600" Height="400"
        Margin="10,10,10,10" VerticalAlignment="Top" />
</Grid>
```

> **Note**
>
> You can also add these and other wrapped controls to the **Window** by dragging them to the designer from the **Windows Community Toolkit** section of the **Toolbox**.

4. Save `MainWindow.xaml`.

   If you have a device that supports a digital pen (such as a Surface), and you're following along on a physical machine, then you could now build and run the app, and draw digital ink on the screen with the pen. But if you try to write with your mouse, then nothing will happen, because by default **InkCanvas** is enabled only for digital pens. Here's how to enable **InkCanvas** for the mouse.

5. Still in *MyWPFApp*, open `MainWindow.xaml.cs`.

6. Add the following namespace directive to the top of the file:

```
C#

using Microsoft.Toolkit.Win32.UI.Controls.Interop.WinRT;
```

7. Locate the **MainWindow** constructor. Immediately after the call to **InitializeComponent**, add the following line of code:

```
C#

myInkCanvas.InkPresenter.InputDeviceTypes = CoreInputDeviceTypes.Mouse
| CoreInputDeviceTypes.Pen;
```

   You can use the **InkPresenter** object to customize the default inking experience. The code above uses the **InputDeviceTypes** property to enable mouse as well as pen input.

8. Save, build, and run. If you're using a computer with a mouse, then confirm that you can draw something in the ink canvas space with the mouse.

Host a CalendarView by using the host control

In this section, we'll use the WindowsXamlHost control to add a CalendarView to the app.

> **Note**
>
> The WindowsXamlHost control is provided by the Microsoft.Toolkit.Wpf.UI.XamlHost package. That package is included with the Microsoft.Toolkit.Wpf.UI.Controls package that you installed earlier.

1. In **Solution Explorer**, in *MyWPFApp*, open the `MainWindow.xaml` file.

2. In the **Window** element near the top of the XAML file, add the following attribute. This attribute references the XAML namespace for the **WindowsXamlHost** control, and maps it to the **xamlhost** XML namespace.

```
XML
```

```
xmlns:xamlhost="clr-
namespace:Microsoft.Toolkit.Wpf.UI.XamlHost;assembly=Microsoft.Toolkit.
Wpf.UI.XamlHost"
```

3. Still in `MainWindow.xaml`, edit the existing **Grid** element so that it looks like the XAML below. This XAML adds to the **Grid** a **WindowsXamlHost** control (prefixed by the **xamlhost** XML namespace that you defined in the previous step). To host a UWP **CalendarView** control, this XAML sets the **InitialTypeName** property to the fully-qualified name of the control. The XAML also defines an event handler for the **ChildChanged** event, which is raised when the hosted control has been rendered.

```
XML

<Grid Margin="10,50,10,10">
    <xamlhost:WindowsXamlHost x:Name="myCalendar"
InitialTypeName="Windows.UI.Xaml.Controls.CalendarView"
          Margin="10,10,10,10" Width="600" Height="300"
ChildChanged="MyCalendar_ChildChanged" />
</Grid>
```

4. Save `MainWindow.xaml`, and open `MainWindow.xaml.cs`.

5. Delete this line of code, which we added in the previous section: `myInkCanvas.InkPresenter.InputDeviceTypes = CoreInputDeviceTypes.Mouse | CoreInputDeviceTypes.Pen;`.

6. Add the following namespace directive to the top of the file:

```
C#

using Microsoft.Toolkit.Wpf.UI.XamlHost;
```

7. Add the following **ChildChanged** event handler method to the **MainWindow** class. When the host control has been rendered, this event handler runs and creates a simple event handler for the **SelectedDatesChanged** event of the calendar control.

```
C#

private void MyCalendar_ChildChanged(object sender, EventArgs e)
{
    WindowsXamlHost windowsXamlHost = (WindowsXamlHost)sender;

    var calendarView =
        (Windows.UI.Xaml.Controls.CalendarView)windowsXamlHost.Child;
```

```
    if (calendarView != null)
    {
        calendarView.SelectedDatesChanged += (obj, args) =>
        {
            if (args.AddedDates.Count > 0)
            {
                MessageBox.Show("The user selected a new date: " +
                    args.AddedDates[0].DateTime.ToString());
            }
        };
    }
}
```

8. Save, build, and run. Confirm that the calendar control is shown in the window, and that a message box is displayed when you select a date.

Package the app

You can optionally package your WPF app in an MSIX package for deployment. MSIX is the modern and reliable app packaging technology for Windows.

The following instructions show you how to package all the components in the solution into an MSIX package by using the **Windows Application Packaging Project** in Visual Studio (see Set up your desktop application for MSIX packaging in Visual Studio). These steps are necessary only if you want to package the WPF app in an MSIX package.

> ⓘ **Note**
>
> If you choose not to package your application in an MSIX package for deployment, then computers that run your app must have the Visual C++ Runtime installed.

1. Add a new project to your solution created from the **Windows Application Packaging Project** project template. As you create the project, select the same **Target version** and **Minimum version** as you selected for the UWP project.

2. In the packaging project, right-click the **Dependencies** node, and choose **Add Project Reference...**. In the list of projects, select *MyWPFApp*, and click **OK**.

   > ⓘ **Note**
   >
   > If you want to publish your app in the Microsoft Store, then you also have to add a reference to the UWP project in the packaging project.

3. If you followed the steps up to this point, then all of the projects in your solution will target the same specific platform (x86 or x64). And that's necessary in order to build the WPF app into an MSIX package using the Windows Application Packaging Project. To confirm that, you can follow these steps:
   a. Right-click the solution node (*not* the project node) in **Solution Explorer**, and choose **Properties**.
   b. Select **Configuration Properties** on the left.
   c. Click the **Configuration Manager...** button.
   d. Confirm that all of the listed projects have the same value under **Platform**: either *x86* or *x64*.

4. Right-click the project node for the packaging project that you just added, and click **Set as Startup project**.

5. Build and run the packaging project. Confirm that the WPF app runs, and that the UWP control(s) display as expected.

6. For info about distributing/deploying the package, see Manage your MSIX deployment.

Host a custom WinRT XAML control in a WPF app using XAML Islands

Article • 08/21/2024

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

This article demonstrates how to use the WindowsXamlHost control in the Windows Community Toolkit to host a custom WinRT XAML control in a WPF app that targets .NET Core 3.1. The custom control contains several first-party controls from the Windows SDK and binds a property in one of the WinRT XAML controls to a string in the WPF app. This article also demonstrates how to also host a control from the WinUI library.

Although this article demonstrates how to do this in a WPF app, the process is similar for a Windows Forms app. For an overview about hosting WinRT XAML controls in WPF and Windows Forms apps, see this article.

> **Note**
>
> Using XAML Islands to host WinRT XAML controls in WPF and Windows Forms apps is currently supported only in apps that target .NET Core 3.x. XAML Islands are not yet supported in apps that target .NET, or in apps that any version of the .NET Framework.

Required components

To host a custom WinRT XAML control in a WPF (or Windows Forms) app, you'll need the following components in your solution. This article provides instructions for creating each of these components.

- **The project and source code for your app**. Using the WindowsXamlHost control to host custom controls is supported only in apps that target .NET Core 3.x.

- **The custom WinRT XAML control**. You'll need the source code for the custom control you want to host so you can compile it with your app. Typically, the custom control is defined in a UWP class library project that you reference in the same solution as your WPF or Windows Forms project.
- **A UWP app project that defines a root Application class that derives from XamlApplication**. Your WPF or Windows Forms project must have access to an instance of the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class provided by the Windows Community Toolkit so that it can discover and load custom UWP XAML controls. The recommended way to do this is to define this object in a separate UWP app project that is part of the solution for your WPF or Windows Forms app.

  > **Note**
  >
  > Your solution can contain only one project that defines a `XamlApplication` object. All custom WinRT XAML controls in your app share the same `XamlApplication` object. The project that defines the `XamlApplication` object must include references to all other WinRT libraries and projects that are used host to controls on the XAML Island.

Create a WPF project

Before getting started, follow these instructions to create a WPF project and configure it to host XAML Islands. If you have an existing WPF project, you can adapt these steps and code examples for your project.

> **Note**
>
> If you have an existing project that targets the .NET Framework, you'll need to migrate your project to .NET Core 3.1. For more information, see this blog series.

1. If you haven't done so already, install the latest version of the .NET Core 3.1 SDK.
2. In Visual Studio 2019, create a new **WPF App (.NET Core)** project.
3. Make sure package references are enabled:
   a. In Visual Studio, click **Tools -> NuGet Package Manager -> Package Manager Settings**.

b. Make sure **PackageReference** is selected for **Default package management format**.

4. Right-click your WPF project in **Solution Explorer** and choose **Manage NuGet Packages**.

5. Select the **Browse** tab, search for the Microsoft.Toolkit.Wpf.UI.XamlHost package and install the latest stable version. This package provides everything you need to use the **WindowsXamlHost** control to host a WinRT XAML control, including other related NuGet packages.

   > **Note**
   >
   > Windows Forms apps must use the Microsoft.Toolkit.Forms.UI.XamlHost package.

6. Configure your solution to target a specific platform such as x86 or x64. Custom WinRT XAML controls are not supported in projects that target **Any CPU**.
   a. In **Solution Explorer**, right-click the solution node and select **Properties** -> **Configuration Properties** -> **Configuration Manager**.
   b. Under **Active solution platform**, select **New**.
   c. In the **New Solution Platform** dialog, select **x64** or **x86** and press **OK**.
   d. Close the open dialog boxes.

Define a XamlApplication class in a UWP app project

Next, add a UWP app project to your solution and revise the default `App` class in this project to derive from the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class provided by the Windows Community Toolkit. This class supports the IXamlMetadataProvider interface, which enables your app to discover and load metadata for custom UWP XAML controls in assemblies in the current directory of your application at run time. This class also initializes the UWP XAML framework for the current thread.

1. In **Solution Explorer**, right-click the solution node and select **Add** -> **New Project**.

2. Add a **Blank App (Universal Windows)** project to your solution. Make sure the target version and minimum version are both set to **Windows 10, version 1903 (Build 18362)** or a later release.

3. In the UWP app project, install the Microsoft.Toolkit.Win32.UI.XamlApplication NuGet package (latest stable version).

4. Open the **App.xaml** file and replace the contents of this file with the following XAML. Replace `MyUWPApp` with the namespace of your UWP app project.

```xml
<xaml:XamlApplication
    x:Class="MyUWPApp.App"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:xaml="using:Microsoft.Toolkit.Win32.UI.XamlHost"
    xmlns:local="using:MyUWPApp">
</xaml:XamlApplication>
```

5. Open the **App.xaml.cs** file and replace the contents of this file with the following code. Replace `MyUWPApp` with the namespace of your UWP app project.

```csharp
namespace MyUWPApp
{
    public sealed partial class App :
Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication
    {
        public App()
        {
            this.Initialize();
        }
    }
}
```

6. Delete the **MainPage.xaml** file from the UWP app project.

7. Clean the UWP app project and then build it.

Add a reference to the UWP project in your WPF project

1. Specify the compatible framework version in the WPF project file.

    a. In **Solution Explorer**, double-click the WPF project node to open the project file in the editor.

b. In the first **PropertyGroup** element, add the following child element. Change the `19041` portion of the value as necessary to match the target and minimum OS build of the UWP project.

```
XML

<AssetTargetFallback>uap10.0.19041</AssetTargetFallback>
```

When you're done, the **PropertyGroup** element should look similar to this.

```
XML

<PropertyGroup>
    <OutputType>WinExe</OutputType>
    <TargetFramework>netcoreapp3.1</TargetFramework>
    <UseWPF>true</UseWPF>
    <Platforms>AnyCPU;x64</Platforms>
    <AssetTargetFallback>uap10.0.19041</AssetTargetFallback>
</PropertyGroup>
```

2. In **Solution Explorer**, right-click the **Dependencies** node under the WPF project and add a reference to your UWP app project.

Instantiate the XamlApplication object in the entry point of your WPF app

Next, add code to the entry point for your WPF app to create an instance of the `App` class you just defined in the UWP project (this is the class that now derives from `XamlApplication`).

1. In your WPF project, right-click the project node, select **Add** -> **New Item**, and then select **Class**. Name the class **Program** and click **Add**.

2. Replace the generated `Program` class with the following code and then save the file. Replace `MyUWPApp` with the namespace of your UWP app project, and replace `MyWPFApp` with the namespace of your WPF app project.

```
C#

public class Program
{
    [System.STAThreadAttribute()]
    public static void Main()
    {
```

```
        using (new MyUWPApp.App())
        {
            MyWPFApp.App app = new MyWPFApp.App();
            app.InitializeComponent();
            app.Run();
        }
    }
}
```

3. Right-click the project node and choose **Properties**.
4. On the **Application** tab of the properties, click the **Startup object** drop-down and choose the fully qualified name of the `Program` class you added in the previous step.

   > **Note**
   >
   > By default, WPF projects define a `Main` entry point function in a generated code file that isn't intended to be modified. This step changes the entry point for your project to the `Main` method of the new `Program` class, which enables you to add code that runs as early in the startup process of the app as possible.

5. Save your changes to the project properties.

Create a custom WinRT XAML control

To host a custom WinRT XAML control in your WPF app, you must have the source code for the control so you can compile it with your app. Typically custom controls are defined in a UWP class library project for easy portability.

In this section, you will define a simple custom control in a new class library project. You can alternatively define the custom control in the UWP app project you created in the previous section. However, these steps do this in a separate class library project for illustrative purposes because this is typically how custom controls are implemented for portability.

If you already have a custom control, you can use it instead of the control shown here. However, you'll still need to configure the project that contains the control as shown in these steps.

1. In **Solution Explorer**, right-click the solution node and select **Add** -> **New Project**.

2. Add a **Class Library (Universal Windows)** project to your solution. Make sure the target version and minimum version are both set to the same target and minimum OS build as the UWP project.

3. Right-click the project file and select **Unload Project**. Right-click the project file again and select **Edit**.

4. Before the closing `</Project>` element, add the following XML to disable several properties and then save the project file. These properties must be enabled to host the custom control in a WPF (or Windows Forms) app.

```
XML

<PropertyGroup>
  <EnableTypeInfoReflection>false</EnableTypeInfoReflection>
  <EnableXBindDiagnostics>false</EnableXBindDiagnostics>
</PropertyGroup>
```

5. Right-click the project file and select **Reload Project**.

6. Delete the default **Class1.cs** file and add a new **User Control** item to the project.

7. In the XAML file for the user control, add the following `StackPanel` as a child of the default `Grid`. This example adds a `TextBlock` control and then binds the `Text` attribute of that control to the `XamlIslandMessage` field.

```
XML

<StackPanel Background="LightCoral">
    <TextBlock>This is a simple custom WinRT XAML control</TextBlock>
    <Rectangle Fill="Blue" Height="100" Width="100"/>
    <TextBlock Text="{x:Bind XamlIslandMessage}" FontSize="50">
</TextBlock>
</StackPanel>
```

8. In the code-behind file for the user control, add the `XamlIslandMessage` field to the user control class as shown below.

```
C#

public sealed partial class MyUserControl : UserControl
{
    public string XamlIslandMessage { get; set; }

    public MyUserControl()
    {
        this.InitializeComponent();
```

```
    }
}
```

9. Build the UWP class library project.
10. In your WPF project, right-click the **Dependencies** node and add a reference to the UWP class library project.
11. In the UWP app project you configured earlier, right-click the **References** node and add a reference to the UWP class library project.
12. Rebuild the entire solution and make sure all the projects build successfully.

Host the custom WinRT XAML control in your WPF app

1. In **Solution Explorer**, expand the WPF project and open the MainWindow.xaml file or some other window in which you want to host the custom control.
2. In the XAML file, add the following namespace declaration to the `<Window>` element.

```
XML

xmlns:xaml="clr-
namespace:Microsoft.Toolkit.Wpf.UI.XamlHost;assembly=Microsoft.Toolkit.
Wpf.UI.XamlHost"
```

3. In the same file, add the following control to the `<Grid>` element. Change the `InitialTypeName` attribute to the fully qualified name of the user control in your UWP class library project.

```
XML

<xaml:WindowsXamlHost InitialTypeName="UWPClassLibrary.MyUserControl"
ChildChanged="WindowsXamlHost_ChildChanged" />
```

4. Open the code-behind file and add the following code to the `Window` class. This code defines a `ChildChanged` event handler that assigns the value of the `XamlIslandMessage` field of the UWP custom control to the value of the `WPFMessage` field in the WPF app. Change `UWPClassLibrary.MyUserControl` to the fully qualified name of the user control in your UWP class library project.

C#

```
private void WindowsXamlHost_ChildChanged(object sender, EventArgs e)
{
    // Hook up x:Bind source.
    global::Microsoft.Toolkit.Wpf.UI.XamlHost.WindowsXamlHost
windowsXamlHost =
        sender as
global::Microsoft.Toolkit.Wpf.UI.XamlHost.WindowsXamlHost;
    global::UWPClassLibrary.MyUserControl userControl =
        windowsXamlHost.GetUwpInternalObject() as
global::UWPClassLibrary.MyUserControl;

    if (userControl != null)
    {
        userControl.XamlIslandMessage = this.WPFMessage;
    }
}

public string WPFMessage
{
    get
    {
        return "Binding from WPF to UWP XAML";
    }
}
```

5. Build and run your app and confirm that the UWP user control displays as expected.

Add a control from the WinUI 2 library to the custom control

Traditionally, WinRT XAML controls have been released as part of the Windows OS and made available to developers through the Windows SDK. The WinUI library is an alternative approach, where updated versions of WinRT XAML controls from the Windows SDK are distributed in a NuGet package that is not tied to Windows SDK releases. This library also includes new controls that aren't part of the Windows SDK and the default UWP platform.

This section demonstrates how to add a WinRT XAML control from the WinUI 2 library to your user control.

> **Note**

Currently, XAML Islands only supports hosting controls from the WinUI 2 library. Support for hosting controls from the WinUI 3 library is coming in a later release.

1. In the UWP app project, install the latest release or prerelease version of the Microsoft.UI.Xaml NuGet package.

   > **Note**
   >
   > If your desktop app is packaged in an **MSIX package**, you can use either a prerelease or release version of the **Microsoft.UI.Xaml** NugGet package. If your desktop app is not packaged using MSIX, you must install a prerelease version of the **Microsoft.UI.Xaml** NuGet package.

2. In the App.xaml file in this project, add the following child element to the `<xaml:XamlApplication>` element.

   XML

   ```
   <Application.Resources>
       <XamlControlsResources xmlns="using:Microsoft.UI.Xaml.Controls" />
   </Application.Resources>
   ```

   After adding this element, the contents of this file should now look similar to this.

   XML

   ```
   <xaml:XamlApplication
       x:Class="MyUWPApp.App"
       xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
       xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
       xmlns:xaml="using:Microsoft.Toolkit.Win32.UI.XamlHost"
       xmlns:local="using:MyUWPApp">
       <Application.Resources>
           <XamlControlsResources xmlns="using:Microsoft.UI.Xaml.Controls"
   />
       </Application.Resources>
   </xaml:XamlApplication>
   ```

3. In the UWP class library project, install the latest version of the Microsoft.UI.Xaml NuGet package (the same version that you installed in the UWP app project).

4. In the same project, open the XAML file for the user control and add the following namespace declaration to the `<UserControl>` element.

XML

```
xmlns:winui="using:Microsoft.UI.Xaml.Controls"
```

5. In the same file, add a `<winui:RatingControl />` element as a child of the `<StackPanel>`. This element adds an instance of the RatingControl class from the WinUI library. After adding this element, the `<StackPanel>` should now look similar to this.

XML

```
<StackPanel Background="LightCoral">
    <TextBlock>This is a simple custom WinRT XAML control</TextBlock>
    <Rectangle Fill="Blue" Height="100" Width="100"/>
    <TextBlock Text="{x:Bind XamlIslandMessage}" FontSize="50">
</TextBlock>
    <winui:RatingControl />
</StackPanel>
```

6. Build and run your app and confirm that the new rating control displays as expected.

Package the app

You can optionally package the WPF app in an MSIX package for deployment. MSIX is the modern app packaging technology for Windows, and it is based on a combination of MSI, .appx, App-V, and ClickOnce installation technologies.

The following instructions show you how to package the all the components in the solution in an MSIX package by using the Windows Application Packaging Project in Visual Studio 2019. These steps are necessary only if you want to package the WPF app in an MSIX package.

> ⓘ **Note**
>
> If you choose to not package your application in an MSIX package for deployment, then computers that run your app must have the Visual C++ Runtime installed.

1. Add a new Windows Application Packaging Project to your solution. As you create the project, select the same **Target version** and **Minimum version** as you selected for the UWP project.

2. In the packaging project, right-click the **Applications** node and choose **Add reference**. In the list of projects, select the WPF project in your solution and click **OK**.

   > ⓘ **Note**
   >
   > If you want to publish your app in the Microsoft Store, you have to add reference to the UWP project in the packaging project.

3. Configure your solution to target a specific platform such as x86 or x64. This is required to build the WPF app into an MSIX package using the Windows Application Packaging Project.
   a. In **Solution Explorer**, right-click the solution node and select **Properties** -> **Configuration Properties** -> **Configuration Manager**.
   b. Under **Active solution platform**, select **x64** or **x86**.
   c. In the row for your WPF project, in the **Platform** column select **New**.
   d. In the **New Solution Platform** dialog, select **x64** or **x86** (the same platform you selected for **Active solution platform**) and click **OK**.
   e. Close the open dialog boxes.

4. Build and run the packaging project. Confirm that the WPF runs and the UWP custom control displays as expected.

5. For info about distributing/deploying the package, see Manage your MSIX deployment.

Resolve "Cannot find a Resource" error when hosting a WinUI control

If you're hosting a custom control that contains a control from the WinUI library, you may encounter a problem where the control cannot be loaded in a packaged app and debugging the code shows the following error.

To resolve this error, copy the **App.xbf** file from the build output folder of the WPF project to the **\AppX\<WPF project>** build output folder of the packaging project.

For example, if the WPF project is named **WPFXamlIslandsApp** and targets x86 platform, copy **App.xbf** from **\WPFXamlIslandsApp\bin\x86\Release\netcoreapp3.1** to **\WPFXamlIslandsApp.Pack\bin\x86\Release\AppX\WPFXamlIslandsAPP**.

Using the WinRT XAML hosting API in a C++ desktop (Win32) app

Article • 08/21/2024

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

Starting in Windows 10, version 1903, non-UWP desktop apps (including C++ desktop (Win32), WPF, and Windows Forms apps) can use the *WinRT XAML hosting API* to host WinRT XAML controls in any UI element that is associated with a window handle (HWND). This API enables non-UWP desktop apps to use the latest Windows UI features that are only available via WinRT XAML controls. For example, non-UWP desktop apps can use this API to host WinRT XAML controls that use the Fluent Design System and support Windows Ink.

The WinRT XAML hosting API provides the foundation for a broader set of controls that we are providing to enable developers to bring Fluent UI to non-UWP desktop apps. This feature is called *XAML Islands*. For an overview of this feature, see Host WinRT XAML controls in desktop apps (XAML Islands).

> **Note**
>
> If you have feedback about XAML Islands, create a new issue in the Microsoft.Toolkit.Win32 repo and leave your comments there.

Is the WinRT XAML hosting API the right choice for your desktop app?

The WinRT XAML hosting API provides the low-level infrastructure for hosting WinRT XAML controls in desktop apps. Some types of desktop apps have the option of using alternative, more convenient APIs to accomplish this goal.

- If you have a C++ desktop app and you want to host WinRT XAML controls in your app, you must use the WinRT XAML hosting API. There are no alternatives for these types of apps.

- For WPF and Windows Forms apps, we strongly recommend that you use the XAML Island .NET controls in the Windows Community Toolkit instead of using the WinRT XAML hosting API directly. These controls use the WinRT XAML hosting API internally and implement all of the behavior you would otherwise need to handle yourself if you used the WinRT XAML hosting API directly, including keyboard navigation and layout changes.

Because we recommend that only C++ desktop apps use the WinRT XAML hosting API, this article primarily provides instructions and examples for C++ desktop apps. However, you can use the WinRT XAML hosting API in WPF and Windows Forms apps if you choose. This article points to relevant source code for the host controls for WPF and Windows Forms in the Windows Community Toolkit so you can see how the WinRT XAML hosting API is used by those controls.

Learn how to use the XAML Hosting API

To follow step-by-step instructions with code examples for using the XAML Hosting API in C++ desktop apps, see these articles:

- Host a standard WinRT XAML control
- Host a custom WinRT XAML control
- Advanced scenarios

Samples

The way you use the WinRT XAML hosting API in your code depends on your app type, the design of your app, and other factors. To help illustrate how to use this API in the context of a complete app, this article refers to code from the following samples.

C++ desktop (Win32)

The following samples demonstrate how to use the WinRT XAML hosting API in a C++ desktop app:

- Simple XAML Island sample. This sample demonstrates a basic implementation of hosting a WinRT XAML control in an unpackaged C++ desktop app.
- XAML Island with custom control sample. This sample demonstrates a complete implementation of hosting a custom WinRT XAML control in a packaged C++ desktop app, as well as handling other behavior such as keyboard input and focus navigation.

WPF and Windows Forms

The WindowsXamlHost control in the Windows Community Toolkit serves as a reference sample for using the WinRT XAML hosting API in WPF and Windows Forms apps. The source code is available at the following locations:

- For the WPF version of the control, go here. The WPF version derives from System.Windows.Interop.HwndHost.
- For the Windows Forms version of the control, go here. The Windows Forms version derives from System.Windows.Forms.Control.

> **Note**
>
> We strongly recommend that you use the **XAML Island .NET controls** in the Windows Community Toolkit instead of using the WinRT XAML hosting API directly in WPF and Windows Forms apps. The WPF and Windows Forms sample links in this article are for illustrative purposes only.

Architecture of the API

The WinRT XAML hosting API includes these main Windows Runtime types and COM interfaces.

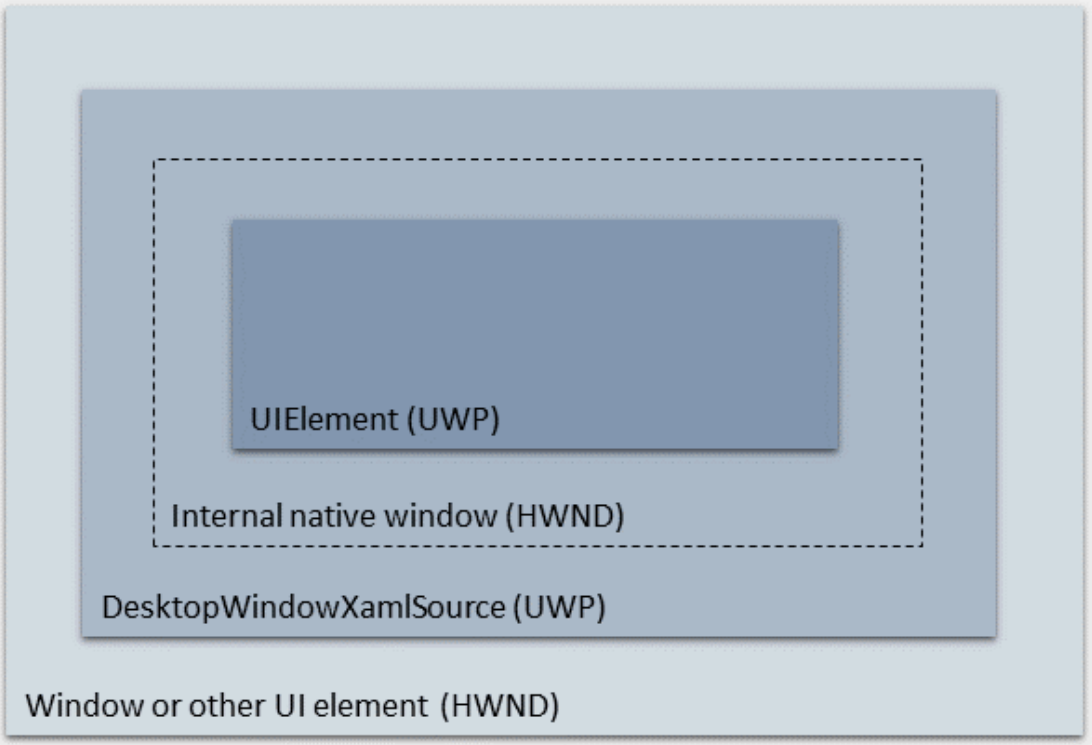
Expand table

Type or interface	Description
WindowsXamlManager	This class represents the UWP XAML framework. This class provides a single static InitializeForCurrentThread method that initializes the UWP XAML framework on the current thread in the desktop app.
DesktopWindowXamlSource	This class represents an instance of UWP XAML content that you are hosting in your desktop app. The most important member of this class is the Content property. You assign this property to a Windows.UI.Xaml.UIElement that you want to host. This class also has other members for routing keyboard focus navigation into and out of the XAML Islands.
IDesktopWindowXamlSourceNative	This COM interface provides the AttachToWindow method, which you use to attach a XAML Island in your app to a

Type or interface	Description
	parent UI element. Every **DesktopWindowXamlSource** object implements this interface.
IDesktopWindowXamlSourceNative2	This COM interface provides the PreTranslateMessage method, which enables the UWP XAML framework to process certain Windows messages correctly. Every **DesktopWindowXamlSource** object implements this interface.

The following diagram illustrates the hierarchy of objects in a XAML Island that is hosted in a desktop app.

- At the base level is the UI element in your app where you want to host the XAML Island. This UI element must have a window handle (HWND). Examples of UI elements in which you can host a XAML Island include a window for C++ desktop apps, a System.Windows.Interop.HwndHost for WPF apps, and a System.Windows.Forms.Control for Windows Forms apps.
- At the next level is a **DesktopWindowXamlSource** object. This object provides the infrastructure for hosting the XAML Island. Your code is responsible for creating this object and attaching it to the parent UI element.
- When you create a **DesktopWindowXamlSource**, this object automatically creates a native child window to host your WinRT XAML control. This native child window is mostly abstracted away from your code, but you can access its handle (HWND) if necessary.
- Finally, at the top level is the WinRT XAML control you want to host in your desktop app. This can be any UWP object that derives from Windows.UI.Xaml.UIElement, including any WinRT XAML control provided by the Windows SDK as well as custom user controls.



Desktop application

> **Note**
>
> When you host XAML Islands in a desktop app, you can have multiple trees of XAML content running on the same thread at the same time. To access the root element of a tree of XAML content in a XAML Island and get related information about the context in which it is hosted, use the **XamlRoot** class. The **CoreWindow**, **ApplicationView**, and **Window** APIs won't provide the correct information for XAML Islands. For more information, see **this section**.

Best practices

When using the WinRT XAML hosting API, follow these best practices for each thread that hosts WinRT XAML controls:

- Create a dedicated WindowsXamlManager for the thread.
- For each WinRT XAML control you want to host, create a DesktopWindowXamlSource.
- Destroy each DesktopWindowXamlSource after it is no longer needed.
- Before exiting the thread, destroy the dedicated WindowsXamlManager for the thread. Note that destruction of this WindowsXamlManager is asynchronous, and

requires draining the Windows message queue before exiting the thread. For examples of how to do this, see the XAML Islands samples.

- After destroying the WindowsXamlManager for a given thread, creating a new WindowsXamlManager on the same thread is not supported and will result in unpredictable behavior.

Troubleshooting

Error using WinRT XAML hosting API in a UWP app

Expand table

Issue	Resolution
Your app receives a **COMException** with the following message: "Cannot activate DesktopWindowXamlSource. This type cannot be used in a UWP app." or "Cannot activate WindowsXamlManager. This type cannot be used in a UWP app."	This error indicates you are trying to use the WinRT XAML hosting API (specifically, you are trying to instantiate the DesktopWindowXamlSource or WindowsXamlManager types) in a UWP app. The WinRT XAML hosting API is only intended to be used in non-UWP desktop apps, such as WPF, Windows Forms, and C++ desktop applications.

Error trying to use the WindowsXamlManager or DesktopWindowXamlSource types

Expand table

Issue	Resolution
Your app receives an exception with the following message: "WindowsXamlManager and DesktopWindowXamlSource are supported for apps targeting Windows version 10.0.18226.0 and later. Please check either the application manifest or package manifest and ensure the MaxTestedVersion property is updated."	This error indicates that your application tried to use the **WindowsXamlManager** or **DesktopWindowXamlSource** types in the WinRT XAML hosting API, but the OS can't determine whether the app was built to target Windows 10, version 1903 or later. The WinRT XAML hosting API was first introduced as a preview in an earlier version of Windows 10, but it is only supported starting in Windows 10, version 1903. To resolve this issue, either create an MSIX package for the app and run it from the package, or install the Microsoft.Toolkit.Win32.UI.SDK NuGet package in your project.

Error attaching to a window on a different thread

Expand table

Issue	Resolution
Your app receives a **COMException** with the following message: "AttachToWindow method failed because the specified HWND was created on a different thread."	This error indicates that your application called the **IDesktopWindowXamlSourceNative::AttachToWindow** method and passed it the HWND of a window that was created on a different thread. You must pass this method the HWND of a window that was created on the same thread as the code from which you are calling the method.

Error attaching to a window on a different top-level window

Expand table

Issue	Resolution
Your app receives a **COMException** with the following message: "AttachToWindow method failed because the specified HWND descends from a different top-level window than the HWND that was previously passed to AttachToWindow on the same thread."	This error indicates that your application called the **IDesktopWindowXamlSourceNative::AttachToWindow** method and passed it the HWND of a window that descends from a different top-level window than a window you specified in a previous call to this method on the same thread. After your application calls **AttachToWindow** on a particular thread, all other DesktopWindowXamlSource objects on the same thread can only attach to windows that are descendants of the same top-level window that was passed in the first call to **AttachToWindow**. When all the **DesktopWindowXamlSource** objects are closed for a particular thread, the next **DesktopWindowXamlSource** is then free to attach to any window again. To resolve this issue, either close all **DesktopWindowXamlSource** objects that are bound to other top-level windows on this thread, or create a new thread for this **DesktopWindowXamlSource**.

Host a standard WinRT XAML control in a C++ desktop (Win32) app

Article • 08/21/2024

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

This article demonstrates how to use the WinRT XAML hosting API to host a standard WinRT XAML control (that is, a control provided by the Windows SDK) in a new C++ desktop app. The code is based on the simple XAML Island sample, and this section discusses some of the most important parts of the code. If you have an existing C++ desktop app project, you can adapt these steps and code examples for your project.

> **Note**
>
> The scenario demonstrated in this article doesn't support directly editing XAML markup for WinRT XAML controls hosted in your app. This scenario restricts you to modifying the appearance and behavior of hosted controls via code. For instructions that enable you to directly edit XAML markup when hosting WinRT XAML controls, see Host a custom WinRT XAML control in a C++ desktop app.

Create a desktop application project

1. In Visual Studio 2019 with the Windows 10, version 1903 SDK (build 10.0.18362) or a later release installed, create a new **Windows Desktop Application** project and name it **MyDesktopWin32App**. This project type is available under the **C++**, **Windows**, and **Desktop** project filters.

2. In **Solution Explorer**, right-click the solution node, click **Retarget solution**, select the **10.0.18362.0** or a later SDK release, and then click **OK**.

3. Install the Microsoft.Windows.CppWinRT NuGet package to enable support for C++/WinRT in your project:
   a. Right-click your project in **Solution Explorer** and choose **Manage NuGet Packages**.

b. Select the **Browse** tab, search for the Microsoft.Windows.CppWinRT package, and install the latest version of this package.

> **Note**
>
> For new projects, you can alternatively install the C++/WinRT Visual Studio Extension (VSIX) and use one of the C++/WinRT project templates included in that extension. For more details, see Visual Studio support for C++/WinRT, and the VSIX.

4. On the **Browse** tab of the **NuGet Package Manager** window, search for the Microsoft.Toolkit.Win32.UI.SDK NuGet package and install the latest stable version of this package. This package provides several build and run time assets that enable XAML Islands to work in your app.

5. Set the `maxversiontested` value in your application manifest to specify that your application is compatible with Windows 10, version 1903.

   a. If you don't already have an application manifest in your project, add a new XML file to your project and name it **app.manifest**.

   b. In your application manifest, include the **compatibility** element and the child elements shown in the following example. Replace the **Id** attribute of the **maxversiontested** element with the version number of Windows you are targeting (this must be 10.0.18362.0 or a later release). Note that setting a higher value means older versions of Windows won't run the app properly because every Windows release only knows of versions before it. If you want the app to run on Windows 10, version 1903 (build 10.0.18362), you should either leave the 10.0.18362.0 value as is, or add multiple **maxversiontested** elements for the different values the app supports.

```xml
<?xml version="1.0" encoding="UTF-8"?>
<assembly xmlns="urn:schemas-microsoft-com:asm.v1"
manifestVersion="1.0">
    <compatibility xmlns="urn:schemas-microsoft-
com:compatibility.v1">
        <application>
            <!-- Windows 10 -->
            <maxversiontested Id="10.0.18362.0"/>
            <supportedOS Id="{8e0f7a12-bfb3-4fe8-b9a5-48fd50a15a9a}"
/>
        </application>
```

```
    </compatibility>
</assembly>
```

6. Add a reference to the Windows Runtime metadata:
   a. In **Solution Explorer**, right-click on your project **References** node and select **Add Reference**.
   b. Click the **Browse** button at the bottom of the page and navigate to the UnionMetadata folder in your SDK install path. By default the SDK will be installed to `C:\Program Files (x86)\Windows Kits\10\UnionMetadata`.
   c. Then, select the folder named after the Windows version you are targeting (e.g. 10.0.18362.0) and inside of that folder pick the `Windows.winmd` file.
   d. Click **OK** to close the **Add Reference** dialog.

Use the XAML hosting API to host a WinRT XAML control

The basic process of using the XAML hosting API to host a WinRT XAML control follows these general steps:

1. Initialize the WinRT XAML framework for the current thread before your app creates any of the Windows.UI.Xaml.UIElement objects that it will host. There are several ways to do this, depending on when you plan to create the DesktopWindowXamlSource object that will host the controls.

   - If your application creates the **DesktopWindowXamlSource** object before it creates any of the **Windows.UI.Xaml.UIElement** objects that it will host, this framework will be initialized for you when you instantiate the **DesktopWindowXamlSource** object. In this scenario, you don't need to add any code of your own to initialize the framework.

   - However, if your application creates the **Windows.UI.Xaml.UIElement** objects before it creates the **DesktopWindowXamlSource** object that will host them, your application must call the static WindowsXamlManager.InitializeForCurrentThread method to explicitly initialize the WinRT XAML framework before the **Windows.UI.Xaml.UIElement** objects are instantiated. Your application should typically call this method when the parent UI element that hosts the **DesktopWindowXamlSource** is instantiated.

> ⓘ **Note**

This method returns a WindowsXamlManager object that contains a reference to the WinRT XAML framework. You can create as many **WindowsXamlManager** objects as you want on a given thread. However, because each object holds a reference to the WinRT XAML framework, you should dispose the objects to ensure that XAML resources are eventually released.

2. Create a DesktopWindowXamlSource object and attach it to a parent UI element in your application that is associated with a window handle.

   To do this, you'll need to follow these steps:

   a. Create a **DesktopWindowXamlSource** object and cast it to the IDesktopWindowXamlSourceNative or IDesktopWindowXamlSourceNative2 COM interface.

   b. Call the AttachToWindow method of the **IDesktopWindowXamlSourceNative** or **IDesktopWindowXamlSourceNative2** interface, and pass in the window handle of the parent UI element in your application.

   > **Important**
   >
   > Make sure that your code calls the **AttachToWindow** method only once per DesktopWindowXamlSource object. Calling this method more than once for a **DesktopWindowXamlSource** object could result in a memory leak.

   c. Set the initial size of the internal child window contained in the **DesktopWindowXamlSource**. By default, this internal child window is set to a width and height of 0. If you don't set the size of the window, any WinRT XAML controls you add to the **DesktopWindowXamlSource** will not be visible. To access the internal child window in the **DesktopWindowXamlSource**, use the **WindowHandle** property of the **IDesktopWindowXamlSourceNative** or **IDesktopWindowXamlSourceNative2** interface.

3. Finally, assign the **Windows.UI.Xaml.UIElement** you want to host to the Content property of your **DesktopWindowXamlSource** object.

The following steps and code examples demonstrate how to do implement the above process:

1. In the **Source Files** folder of the project, open the default **MyDesktopWin32App.cpp** file. Delete the entire contents of the file and add the

following `include` and `using` statements. In addition to standard C++ and UWP headers and namespaces, these statements include several items specific to XAML Islands.

C++/WinRT

```
#include <windows.h>
#include <stdlib.h>
#include <string.h>

#include <winrt/Windows.Foundation.Collections.h>
#include <winrt/Windows.system.h>
#include <winrt/windows.ui.xaml.hosting.h>
#include <windows.ui.xaml.hosting.desktopwindowxamlsource.h>
#include <winrt/windows.ui.xaml.controls.h>
#include <winrt/Windows.ui.xaml.media.h>

using namespace winrt;
using namespace Windows::UI;
using namespace Windows::UI::Composition;
using namespace Windows::UI::Xaml::Hosting;
using namespace Windows::Foundation::Numerics;
```

2. Copy the following code after the previous section. This code defines the **WinMain** function for the app. This function initializes a basic window and uses the XAML hosting API to host a simple UWP **TextBlock** control in the window.

C++/WinRT

```
LRESULT CALLBACK WindowProc(HWND, UINT, WPARAM, LPARAM);

HWND _hWnd;
HWND _childhWnd;
HINSTANCE _hInstance;

int CALLBACK WinMain(_In_ HINSTANCE hInstance, _In_opt_ HINSTANCE
hPrevInstance, _In_ LPSTR lpCmdLine, _In_ int nCmdShow)
{
    _hInstance = hInstance;

    // The main window class name.
    const wchar_t szWindowClass[] = L"Win32DesktopApp";
    WNDCLASSEX windowClass = { };

    windowClass.cbSize = sizeof(WNDCLASSEX);
    windowClass.lpfnWndProc = WindowProc;
    windowClass.hInstance = hInstance;
    windowClass.lpszClassName = szWindowClass;
    windowClass.hbrBackground = (HBRUSH)(COLOR_WINDOW + 1);

    windowClass.hIconSm = LoadIcon(windowClass.hInstance,
```

```
IDI_APPLICATION);

    if (RegisterClassEx(&windowClass) == NULL)
    {
        MessageBox(NULL, L"Windows registration failed!", L"Error",
NULL);
        return 0;
    }

    _hWnd = CreateWindow(
        szWindowClass,
        L"Windows c++ Win32 Desktop App",
        WS_OVERLAPPEDWINDOW | WS_VISIBLE,
        CW_USEDEFAULT, CW_USEDEFAULT, CW_USEDEFAULT, CW_USEDEFAULT,
        NULL,
        NULL,
        hInstance,
        NULL
    );
    if (_hWnd == NULL)
    {
        MessageBox(NULL, L"Call to CreateWindow failed!", L"Error",
NULL);
        return 0;
    }

    // Begin XAML Island section.

    // The call to winrt::init_apartment initializes COM; by default,
in a multithreaded apartment.
    winrt::init_apartment(apartment_type::single_threaded);

    // Initialize the XAML framework's core window for the current
thread.
    WindowsXamlManager winxamlmanager =
WindowsXamlManager::InitializeForCurrentThread();

    // This DesktopWindowXamlSource is the object that enables a non-
UWP desktop application
    // to host WinRT XAML controls in any UI element that is associated
with a window handle (HWND).
    DesktopWindowXamlSource desktopSource;

    // Get handle to the core window.
    auto interop = desktopSource.as<IDesktopWindowXamlSourceNative>();

    // Parent the DesktopWindowXamlSource object to the current window.
    check_hresult(interop->AttachToWindow(_hWnd));

    // This HWND will be the window handler for the XAML Island: A
child window that contains XAML.
    HWND hWndXamlIsland = nullptr;

    // Get the new child window's HWND.
```

```
    interop->get_WindowHandle(&hWndXamlIsland);

    // Update the XAML Island window size because initially it is 0,0.
    SetWindowPos(hWndXamlIsland, 0, 200, 100, 800, 200,
SWP_SHOWWINDOW);

    // Create the XAML content.
    Windows::UI::Xaml::Controls::StackPanel xamlContainer;
    xamlContainer.Background(Windows::UI::Xaml::Media::SolidColorBrush{
Windows::UI::Colors::LightGray() });

    Windows::UI::Xaml::Controls::TextBlock tb;
    tb.Text(L"Hello World from Xaml Islands!");
    tb.VerticalAlignment(Windows::UI::Xaml::VerticalAlignment::Center);

tb.HorizontalAlignment(Windows::UI::Xaml::HorizontalAlignment::Center);
    tb.FontSize(48);

    xamlContainer.Children().Append(tb);
    xamlContainer.UpdateLayout();
    desktopSource.Content(xamlContainer);

    // End XAML Island section.

    ShowWindow(_hWnd, nCmdShow);
    UpdateWindow(_hWnd);

    //Message loop:
    MSG msg = { };
    while (GetMessage(&msg, NULL, 0, 0))
    {
        TranslateMessage(&msg);
        DispatchMessage(&msg);
    }

    return 0;
}
```

3. Copy the following code after the previous section. This code defines the window procedure for the window.

C++/WinRT

```
LRESULT CALLBACK WindowProc(HWND hWnd, UINT messageCode, WPARAM wParam,
LPARAM lParam)
{
    PAINTSTRUCT ps;
    HDC hdc;
    wchar_t greeting[] = L"Hello World in Win32!";
    RECT rcClient;

    switch (messageCode)
    {
```

```
        case WM_PAINT:
            if (hWnd == _hWnd)
            {
                hdc = BeginPaint(hWnd, &ps);
                TextOut(hdc, 300, 5, greeting, wcslen(greeting));
                EndPaint(hWnd, &ps);
            }
            break;
        case WM_DESTROY:
            PostQuitMessage(0);
            break;

        // Create main window
        case WM_CREATE:
            _childhWnd = CreateWindowEx(0, L"ChildWClass", NULL,
WS_CHILD | WS_BORDER, 0, 0, 0, 0, hWnd, NULL, _hInstance, NULL);
            return 0;

        // Main window changed size
        case WM_SIZE:
            // Get the dimensions of the main window's client
            // area, and enumerate the child windows. Pass the
            // dimensions to the child windows during enumeration.
            GetClientRect(hWnd, &rcClient);
            MoveWindow(_childhWnd, 200, 200, 400, 500, TRUE);
            ShowWindow(_childhWnd, SW_SHOW);

            return 0;

            // Process other messages.

        default:
            return DefWindowProc(hWnd, messageCode, wParam, lParam);
            break;
    }

    return 0;
}
```

4. Save the code file, and build and run the app. Confirm that you see the UWP **TextBlock** control in the app window.

> **Note**
>
> You may see the several build warnings, including `warning C4002: too many arguments for function-like macro invocation 'GetCurrentTime'` and `manifest authoring warning 81010002: Unrecognized Element "maxversiontested" in namespace "urn:schemas-microsoft-`

`com:compatibility.v1"`. These warnings are known issues with the current tools and NuGet packages, and they can be ignored.

For complete examples that demonstrate using the XAML hosting API to host a WinRT XAML control, see the following code files:

- **C++ desktop (Win32):** See the XamlBridge.cpp file in the XAML Islands code samples repo.
- **WPF:** See the WindowsXamlHostBase.cs and WindowsXamlHost.cs files in the Windows Community Toolkit.
- **Windows Forms:** See the WindowsXamlHostBase.cs and WindowsXamlHost.cs files in the Windows Community Toolkit.

Package the app

You can optionally package the app in an MSIX package for deployment. MSIX is the modern app packaging technology for Windows, and it is based on a combination of MSI, .appx, App-V and ClickOnce installation technologies.

The following instructions show you how to package the all the components in the solution in an MSIX package by using the Windows Application Packaging Project in Visual Studio 2019. These steps are necessary only if you want to package the app in an MSIX package.

> **Note**
>
> If you choose to not package your application in an MSIX package for deployment, then computers that run your app must have the Visual C++ Runtime installed.

1. Add a new Windows Application Packaging Project to your solution. As you create the project, select **Windows 10, version 1903 (10.0; Build 18362)** for both the **Target version** and **Minimum version**.

2. In the packaging project, right-click the **Applications** node and choose **Add reference**. In the list of projects, select the C++ desktop application project in your solution and click **OK**.

3. Build and run the packaging project. Confirm that the app runs and displays the WinRT XAML controls as expected.

4. For info about distributing/deploying the package, see Manage your MSIX deployment.

Next steps

The code examples in this article get you started with the basic scenario of hosting a standard WinRT XAML control in a C++ desktop app. The following sections introduce additional scenarios that your application may need to support.

Host a custom WinRT XAML control

For many scenarios, you may need to host a custom WinRT XAML control that contains several individual controls that work together. The process for hosting a custom control (either a control you define yourself or a control provided by a 3rd party) in a C++ desktop app is more complex than hosting a standard control, and requires additional code.

For a complete walkthrough, see Host a custom WinRT XAML control in a C++ desktop app using the XAML Hosting API.

Advanced scenarios

Many desktop applications that host XAML Islands will need to handle additional scenarios in order to provide a smooth user experience. For example, desktop applications may need to handle keyboard input in XAML Islands, focus navigation between XAML Islands and other UI elements, and layout changes.

For more information about handling these scenarios and pointers to related code samples, see Advanced scenarios for XAML Islands in C++ desktop apps.

Host a custom WinRT XAML control in a C++ desktop (Win32) app

Article • 02/27/2025

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

This article demonstrates how to use the WinRT XAML hosting API to host a custom WinRT XAML control in a new C++ desktop app. If you have an existing C++ desktop app project, you can adapt these steps and code examples for your project.

To host a custom WinRT XAML control, you'll create the following projects and components as part of this walkthrough:

- **Windows Desktop Application project**. This project implements a native C++ desktop app. You'll add code to this project that uses the WinRT XAML hosting API to host a custom WinRT XAML control.
- **UWP app project (C++/WinRT)**. This project implements a custom WinRT XAML control. It also implements a root metadata provider for loading metadata for custom WinRT XAML types in the project.

Requirements

- Visual Studio 2019 version 16.4.3 or later.
- Windows 10, version 1903 SDK (version 10.0.18362) or later.
- C++/WinRT Visual Studio Extension (VSIX) installed with Visual Studio. C++/WinRT is an entirely standard modern C++17 language projection for Windows Runtime (WinRT) APIs, implemented as a header-file-based library, and designed to provide you with first-class access to the modern Windows API. For more information, see C++/WinRT.

Create a desktop application project

1. In Visual Studio, create a new **Windows Desktop Application** project named **MyDesktopWin32App**. This project template is available under the **C++**, **Windows**,

and **Desktop** project filters.

2. In **Solution Explorer**, right-click the solution node, click **Retarget solution**, select the **10.0.18362.0** or a later SDK release, and then click **OK**.

3. Install the Microsoft.Windows.CppWinRT NuGet package to enable support for C++/WinRT in your project:
   a. Right-click the **MyDesktopWin32App** project in **Solution Explorer** and choose **Manage NuGet Packages**.
   b. Select the **Browse** tab, search for the Microsoft.Windows.CppWinRT package, and install the latest version of this package.

4. In the **Manage NuGet Packages** window, install the following additional NuGet packages:

   - Microsoft.Toolkit.Win32.UI.SDK (latest stable version). This package provides several build and run time assets that enable XAML Islands to work in your app.
   - Microsoft.Toolkit.Win32.UI.XamlApplication (latest stable version). This package defines the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class, which you will use later in this walkthrough.
   - Microsoft.VCRTForwarders.140.

5. Add a reference to the Windows Runtime metadata:
   a. In **Solution Explorer**, right-click on your project **References** node and select **Add Reference**.
   b. Click the **Browse** button at the bottom of the page and navigate to the UnionMetadata folder in your SDK install path. By default the SDK will be installed to `C:\Program Files (x86)\Windows Kits\10\UnionMetadata`.
   c. Then, select the folder named after the Windows version you are targetting (e.g. 10.0.18362.0) and inside of that folder pick the `Windows.winmd` file.
   d. Click **OK** to close the **Add Reference** dialog.

6. Build the solution and confirm that it builds successfully.

Create a UWP app project

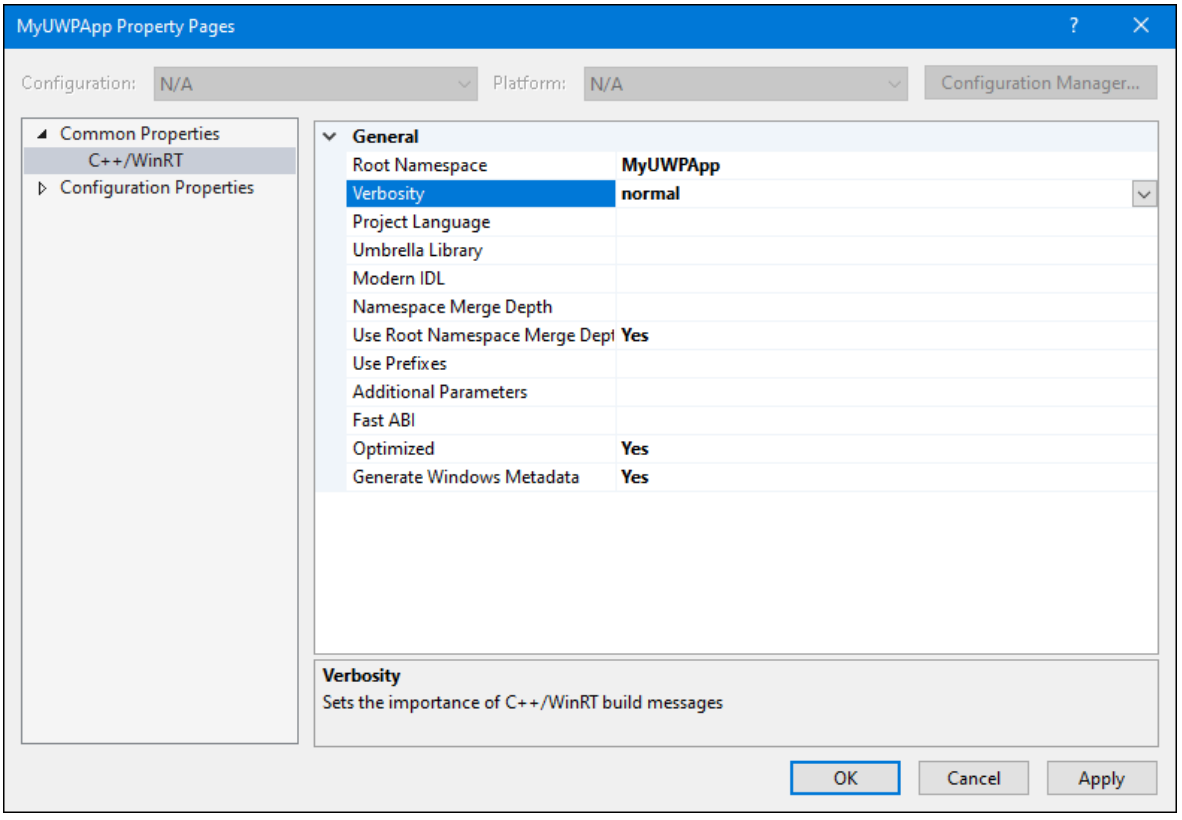
Next, add a **UWP (C++/WinRT)** app project to your solution and make some configuration changes to this project. Later in this walkthrough, you'll add code to this project to implement a custom WinRT XAML control and define an instance of the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class.

1. In **Solution Explorer**, right-click the solution node and select **Add** -> **New Project**.

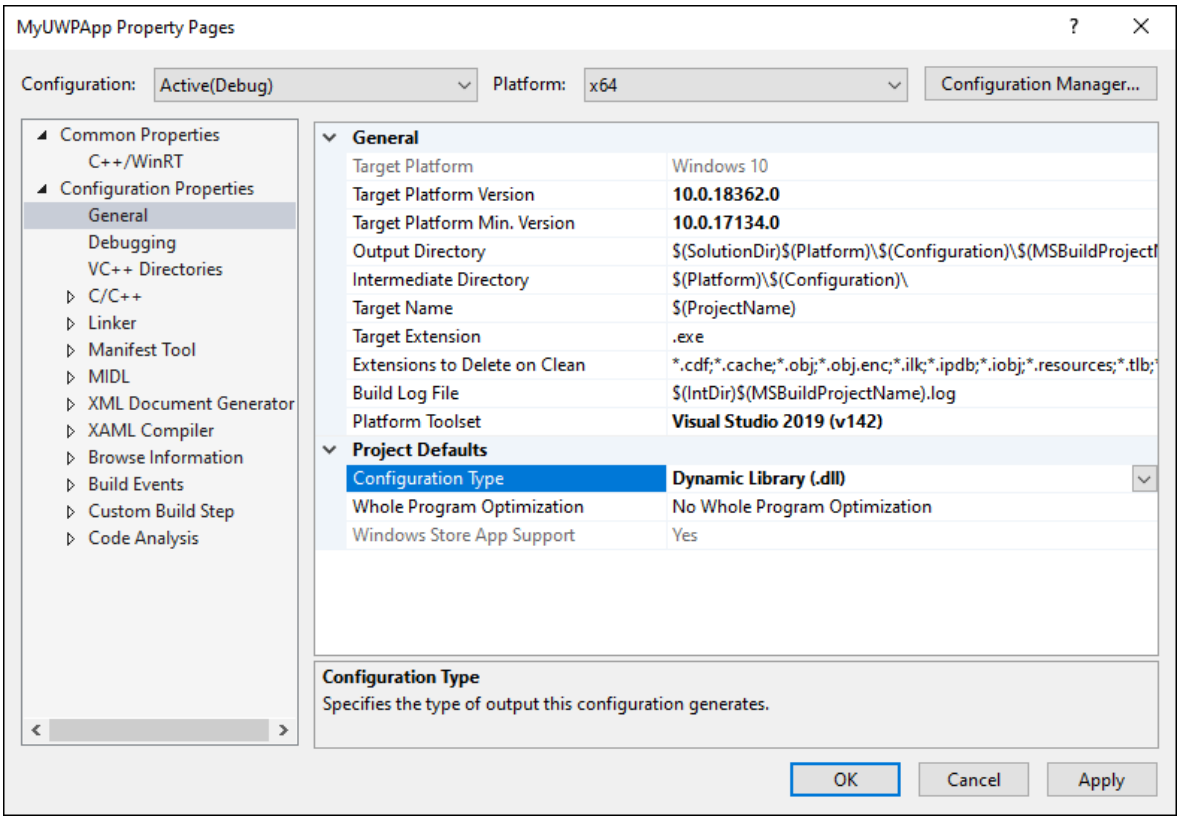
2. Add a **Blank App (C++/WinRT)** project to your solution. Name the project **MyUWPApp** and make sure the target version and minimum version are both set to **Windows 10, version 1903** or later.

3. Install the Microsoft.Toolkit.Win32.UI.XamlApplication NuGet package in the **MyUWPApp** project. This package defines the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class, which you will use later in this walkthrough.
   a. Right-click the **MyUWPApp** project and choose **Manage NuGet Packages**.
   b. Select the **Browse** tab, search for the Microsoft.Toolkit.Win32.UI.XamlApplication package, and install the latest stable version of this package.

4. Right-click the **MyUWPApp** node and select **Properties**. On the **Common Properties** -> **C++/WinRT** page, set the **Verbosity** property to **normal** and then click **Apply**. When you are done, the properties page should look like this.



5. On the **Configuration Properties** -> **General** page of the properties window, set **Configuration Type** to **Dynamic Library (.dll)**, and then click **OK** to close the properties window.



6. Add a placeholder executable file to the **MyUWPApp** project. This placeholder executable file is required for Visual Studio to generate the required project files and properly build the project.

   a. In **Solution Explorer**, right-click the **MyUWPApp** project node and select **Add -> New Item**.

   b. In the **Add New Item** dialog, select **Utility** in the left page, and then select **Text File (.txt)**. Enter the name **placeholder.exe** and click **Add**.

   c. In **Solution Explorer**, select the **placeholder.exe** file. In the **Properties** window, make sure the **Content** property is set to **True**.

d. In **Solution Explorer**, right-click the **Package.appxmanifest** file in the **MyUWPApp** project, select **Open With**, and select **XML (Text) Editor**, and click **OK**.

e. Find the **<Application>** element and change the **Executable** attribute to the value `placeholder.exe`. When you are done, the **<Application>** element should look similar to this.

```
XML

<Application Id="App" Executable="placeholder.exe"
EntryPoint="MyUWPApp.App">
  <uap:VisualElements DisplayName="MyUWPApp" Description="Project
for a single page C++/WinRT Universal Windows Platform (UWP) app
with no predefined layout"
    Square150x150Logo="Assets\Square150x150Logo.png"
Square44x44Logo="Assets\Square44x44Logo.png"
BackgroundColor="transparent">
    <uap:DefaultTile Wide310x150Logo="Assets\Wide310x150Logo.png">
    </uap:DefaultTile>
    <uap:SplashScreen Image="Assets\SplashScreen.png" />
  </uap:VisualElements>
</Application>
```

f. Save and close the **Package.appxmanifest** file.

7. In **Solution Explorer**, right-click the **MyUWPApp** node and select **Unload Project**.

8. Right-click the **MyUWPApp** node and select **Edit MyUWPApp.vcxproj**.

9. Find the `<Import Project="$(VCTargetsPath)\Microsoft.Cpp.Default.props" />` element and replace it with the following XML. This XML adds several new properties immediately before the element.

```
XML

<PropertyGroup Label="Globals">
    <WindowsAppContainer>true</WindowsAppContainer>
    <AppxGeneratePriEnabled>true</AppxGeneratePriEnabled>
    <ProjectPriIndexName>App</ProjectPriIndexName>
    <AppxPackage>true</AppxPackage>
</PropertyGroup>
<Import Project="$(VCTargetsPath)\Microsoft.Cpp.Default.props" />
```

10. Save and close the project file.

11. In **Solution Explorer**, right-click the **MyUWPApp** node and select **Reload Project**.

Configure the solution

In this section, you'll update the solution that contains both projects to configure project dependencies and build properties required for the projects to build correctly.

1. In **Solution Explorer**, right-click the solution node and add a new XML file named **Solution.props**.

2. Add the following XML to the **Solution.props** file.

```XML
<?xml version="1.0" encoding="utf-8"?>
<Project xmlns="http://schemas.microsoft.com/developer/msbuild/2003">
  <PropertyGroup>

<IntDir>$(SolutionDir)\obj\$(Platform)\$(Configuration)\$(MSBuildProjec
tName)\</IntDir>

<OutDir>$(SolutionDir)\bin\$(Platform)\$(Configuration)\$(MSBuildProjec
tName)\</OutDir>
    <GeneratedFilesDir>$(IntDir)Generated Files\</GeneratedFilesDir>
  </PropertyGroup>
</Project>
```

3. From the **View** menu, click **Property Manager** (depending on your configuration, this may be under **View** -> **Other Windows**).

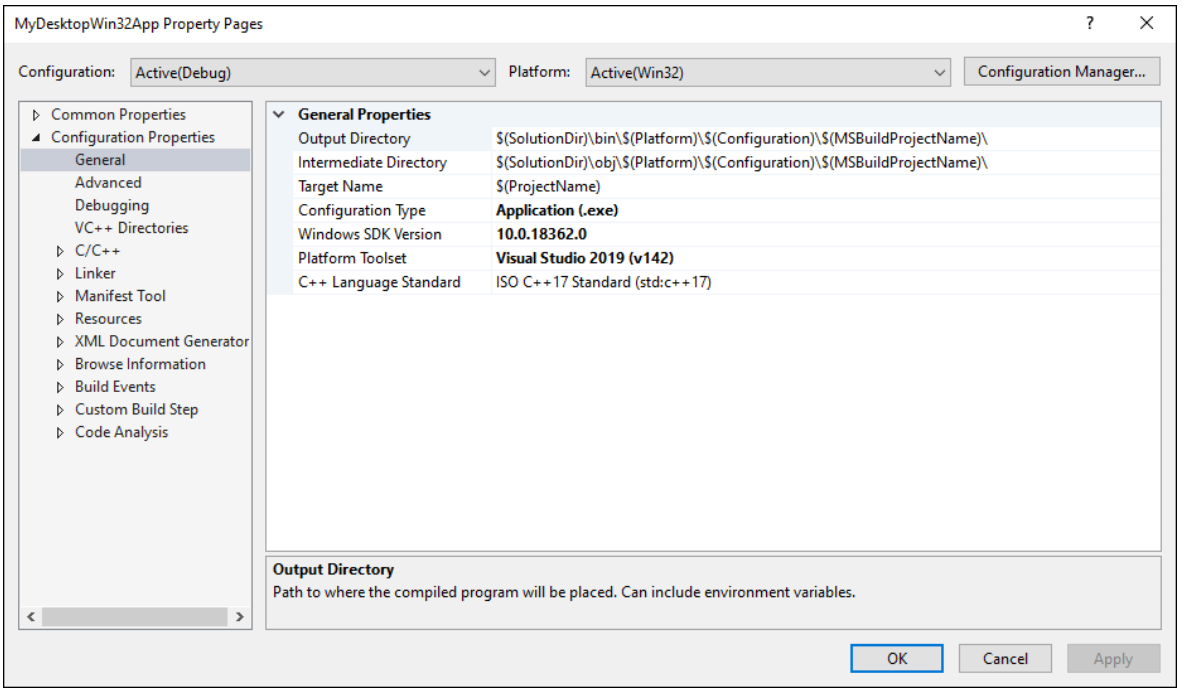
4. In the **Property Manager** window, right-click **MyDesktopWin32App** and select **Add Existing Property Sheet**. Navigate to the **Solution.props** file you just added and click **Open**.

5. Repeat the previous step to add the **Solution.props** file to the **MyUWPApp** project in the **Property Manager** window.

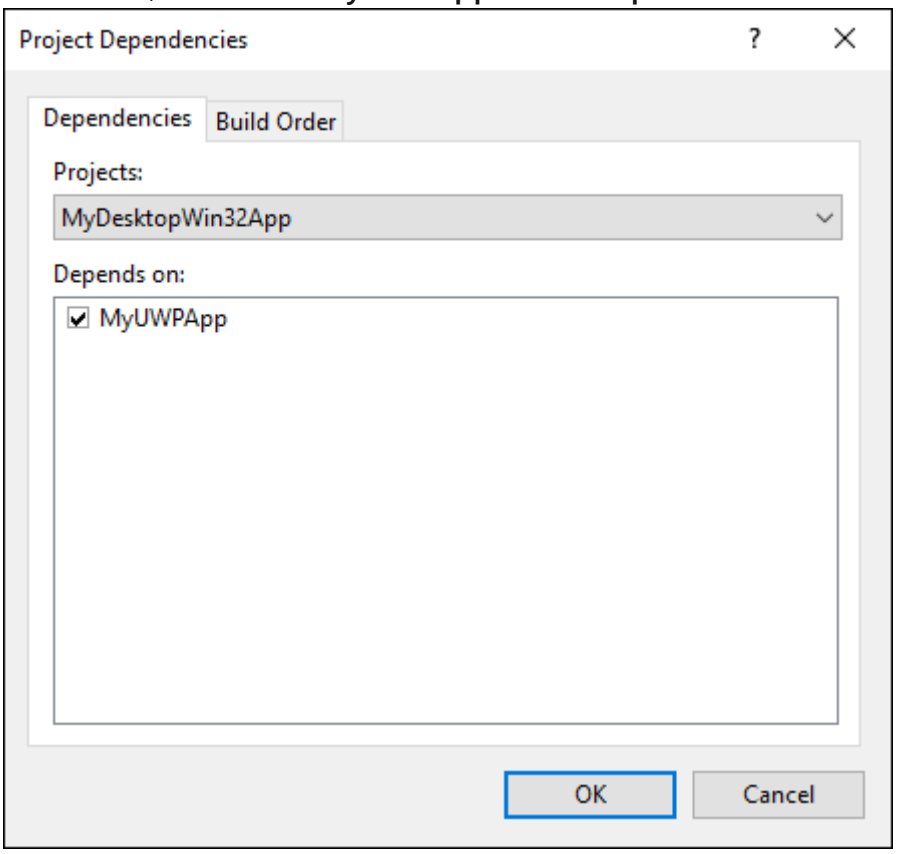
6. Close the **Property Manager** window.

7. Confirm that the property sheet changes were saved properly. In **Solution Explorer**, right-click the **MyDesktopWin32App** project and choose **Properties**. Click **Configuration Properties** -> **General**, and confirm that the **Output Directory** and **Intermediate Directory** properties have the values you added to the

Solution.props file. You can also confirm the same for the **MyUWPApp** project.



8. In **Solution Explorer**, right-click the solution node and choose **Project Dependencies**. In the **Projects** drop-down, make sure that **MyDesktopWin32App** is selected, and select **MyUWPApp** in the **Depends On** list.



9. Click **OK**.

Add code to the UWP app project

You're now ready to add code to the **MyUWPApp** project to perform these tasks:

- Implement a custom WinRT XAML control. Later in this walkthrough, you'll add code that hosts this control in the **MyDesktopWin32App** project.
- Define a type that derives from the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class in the Windows Community Toolkit.

Define a custom WinRT XAML control

1. In **Solution Explorer**, right-click **MyUWPApp** and select **Add** -> **New Item**. Select the **Visual C++** node in the left pane, select **Blank User Control (C++/WinRT)**, name it **MyUserControl**, and click **Add**.

2. In the XAML editor, replace the contents of the **MyUserControl.xaml** file with the following XAML and then save the file.

XML

```
<UserControl
    x:Class="MyUWPApp.MyUserControl"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:MyUWPApp"
    xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
    xmlns:mc="http://schemas.openxmlformats.org/markup-
compatibility/2006"
    mc:Ignorable="d">

    <StackPanel HorizontalAlignment="Center" Spacing="10"
                Padding="20" VerticalAlignment="Center">
        <TextBlock HorizontalAlignment="Center" TextWrapping="Wrap"
                       Text="Hello from XAML Islands" FontSize="30" />
        <TextBlock HorizontalAlignment="Center" Margin="15"
TextWrapping="Wrap"
                       Text="😍❤💋🌹🎉😎🏴" FontSize="16" />
        <Button HorizontalAlignment="Center"
                x:Name="Button" Click="ClickHandler">Click Me</Button>
    </StackPanel>
</UserControl>
```

Define a XamlApplication class

Next, revise the default **App** class in the **MyUWPApp** project to derive from the Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication class provided by the Windows Community Toolkit. This class supports the IXamlMetadataProvider interface, which enables your app to discover and load metadata for custom WinRT XAML controls in assemblies in the current directory of your application at run time. This class also

initializes the WinRT XAML framework for the current thread. Later in this walkthrough you'll update the desktop project to create an instance of this class.

> ⓘ **Note**
>
> Each solution that uses XAML Islands can contain only one project that defines a `XamlApplication` object. All custom WinRT XAML controls in your app share the same `XamlApplication` object.

1. In **Solution Explorer**, right-click the **MainPage.xaml** file in the **MyUWPApp** project. Click **Remove** and then **Delete** to delete this file permanently from the project.
2. In the **MyUWPApp** project, expand **App.xaml** file.
3. Replace the contents of the **App.xaml**, **App.cpp**, **App.h**, and **App.idl** files with the following code.

   - **App.xaml**:

     XML

     ```
     <Toolkit:XamlApplication
         x:Class="MyUWPApp.App"
         xmlns:Toolkit="using:Microsoft.Toolkit.Win32.UI.XamlHost"

     xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
         xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
         xmlns:local="using:MyUWPApp">
     </Toolkit:XamlApplication>
     ```

   - **App.idl**:

     IDL

     ```
     namespace MyUWPApp
     {
          [default_interface]
          runtimeclass App :
     Microsoft.Toolkit.Win32.UI.XamlHost.XamlApplication
          {
             App();
          }
     }
     ```

   - **App.h**:

```C++
#pragma once
#include "App.g.h"
#include "App.base.h"
namespace winrt::MyUWPApp::implementation
{
    class App : public AppT2<App>
    {
    public:
        App();
        ~App();
    };
}
namespace winrt::MyUWPApp::factory_implementation
{
    class App : public AppT<App, implementation::App>
    {
    };
}
```

- **App.cpp**:

```C++
#include "pch.h"
#include "App.h"
#include "App.g.cpp"
using namespace winrt;
using namespace Windows::UI::Xaml;
namespace winrt::MyUWPApp::implementation
{
    App::App()
    {
        Initialize();
        AddRef();
        m_inner.as<::IUnknown>()->Release();
    }
    App::~App()
    {
        Close();
    }
}
```

> ⓘ **Note**
>
> The `#include "App.g.cpp"` statement is necessary when the **Optimized** property on the **Common Properties** -> **C++/WinRT** page of the project properties is set to **Yes**. This is the default for new C++/WinRT projects.

> For more details about the effects of the **Optimized** property, see this section.

4. Add a new header file to the **MyUWPApp** project named **app.base.h**.

5. Add the following code to the **app.base.h** file, save the file, and close it.

```
C++
```

```
#pragma once
namespace winrt::MyUWPApp::implementation
{
    template <typename D, typename... I>
    struct App_baseWithProvider : public App_base<D,
::winrt::Windows::UI::Xaml::Markup::IXamlMetadataProvider>
    {
        using IXamlType =
::winrt::Windows::UI::Xaml::Markup::IXamlType;
        IXamlType
GetXamlType(::winrt::Windows::UI::Xaml::Interop::TypeName const& type)
        {
            return _appProvider.GetXamlType(type);
        }
        IXamlType GetXamlType(::winrt::hstring const& fullName)
        {
            return _appProvider.GetXamlType(fullName);
        }

::winrt::com_array<::winrt::Windows::UI::Xaml::Markup::XmlnsDefinition>
GetXmlnsDefinitions()
        {
            return _appProvider.GetXmlnsDefinitions();
        }
    private:
        bool _contentLoaded{ false };
        winrt::MyUWPApp::XamlMetaDataProvider _appProvider;
    };
    template <typename D, typename... I>
    using AppT2 = App_baseWithProvider<D, I...>;
}
```

6. Build the solution and confirm that it builds successfully.

Configure the desktop project to consume custom control types

Before the **MyDesktopWin32App** app can host a custom WinRT XAML control in a XAML Island, it must be configured to consume custom control types from the

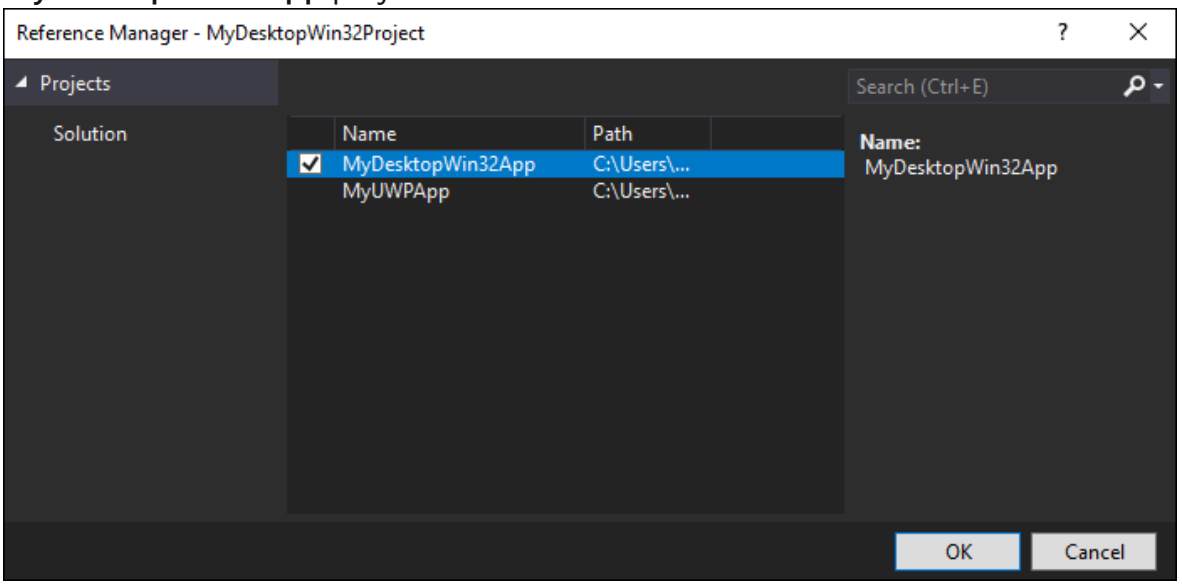
MyUWPApp project. There are two ways to do this, and you can choose either option as you complete this walkthrough.

Option 1: Package the app using MSIX

You can package the app in an MSIX package for deployment. MSIX is the modern app packaging technology for Windows, and it is based on a combination of MSI, .appx, App-V and ClickOnce installation technologies.

1. Add a new Windows Application Packaging Project to your solution. As you create the project, name it **MyDesktopWin32Project** and select **Windows 10, version 1903 (10.0; Build 18362)** for both the **Target version** and **Minimum version**.

2. In the packaging project, right-click the **Applications** node and choose **Add reference**. In the list of projects, select the check box next to the **MyDesktopWin32App** project and click **OK**.



3. For info about distributing/deploying the package, see Manage your MSIX deployment.

> ⓘ **Note**
>
> If you choose to not package your application in an MSIX package for deployment, then computers that run your app must have the Visual C++ Runtime installed.

Option 2: Create an application manifest

You can add an application manifest to your app.

1. Right-click the **MyDesktopWin32App** project and select **Add** -> **New Item**.

2. In the **Add New Item** dialog, click **Web** in the left pane and select **XML File (.xml)**.

3. Name the new file **app.manifest** and click **Add**.

4. Replace the contents of the new file with the following XML. This XML registers custom control types in the **MyUWPApp** project.

XML

```xml
<?xml version="1.0" encoding="utf-8"?>
<assembly
 xmlns="urn:schemas-microsoft-com:asm.v1"
 xmlns:asmv3="urn:schemas-microsoft-com:asm.v3"
 manifestVersion="1.0">
  <asmv3:file name="MyUWPApp.dll">
    <activatableClass
        name="MyUWPApp.App"
        threadingModel="both"
        xmlns="urn:schemas-microsoft-com:winrt.v1" />
    <activatableClass
        name="MyUWPApp.XamlMetadataProvider"
        threadingModel="both"
        xmlns="urn:schemas-microsoft-com:winrt.v1" />
    <activatableClass
        name="MyUWPApp.MyUserControl"
        threadingModel="both"
        xmlns="urn:schemas-microsoft-com:winrt.v1" />
  </asmv3:file>
</assembly>
```

Configure additional desktop project properties

Next, update the **MyDesktopWin32App** project to define a macro for additional include directories and configure additional properties.

1. In **Solution Explorer**, right-click the **MyDesktopWin32App** project and select **Unload Project**.

2. Right-click **MyDesktopWin32App (Unloaded)** and select **Edit MyDesktopWin32App.vcxproj**.

3. Add the following XML just before the closing `</Project>` tag at the end of the file. Then, save and close the file.

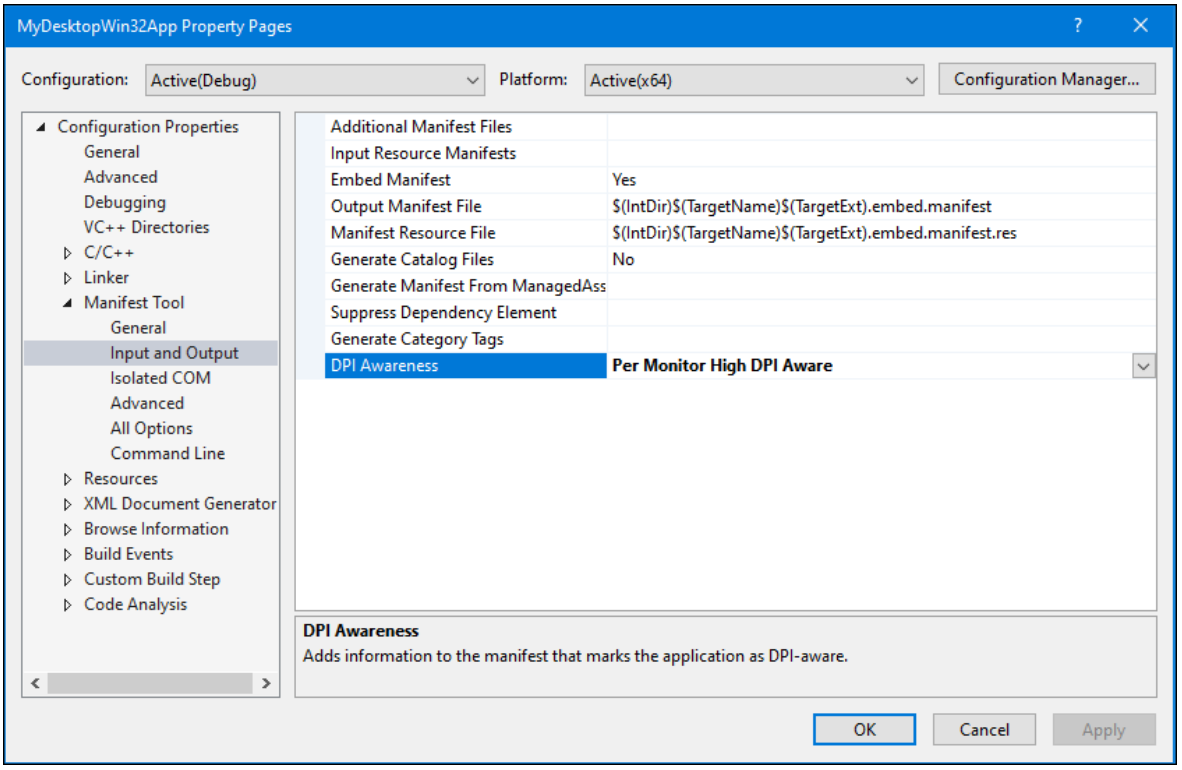
XML

```
  <!-- Configure these for your UWP project -->
  <PropertyGroup>
    <AppProjectName>MyUWPApp</AppProjectName>
  </PropertyGroup>
  <PropertyGroup>

<AppIncludeDirectories>$(SolutionDir)\obj\$(Platform)\$(Configuration)\
$(AppProjectName)\;$(SolutionDir)\obj\$(Platform)\$(Configuration)\$(Ap
pProjectName)\Generated Files\;</AppIncludeDirectories>
  </PropertyGroup>
  <ItemGroup>
    <ProjectReference
Include="..\$(AppProjectName)\$(AppProjectName).vcxproj" />
  </ItemGroup>
  <!-- End Section-->
```

4. In **Solution Explorer**, right-click **MyDesktopWin32App (unloaded)** and select **Reload Project**.

5. Right-click the **MyDesktopWin32App** project, select **Properties**, and expand **Manifest Tool** -> **Input and Output** in the left pane. Set the **DPI Awareness** property to **Per Monitor High DPI Aware**. If you do not set this property, you may encounter a manifest configuration error in certain high DPI scenarios.



6. Click **OK** to close the **Property Pages** dialog.

Host the custom WinRT XAML control in the desktop project

Finally, you're ready to add code to the **MyDesktopWin32App** project to host the custom WinRT XAML control you defined earlier in the **MyUWPApp** project.

1. In the **MyDesktopWin32App** project, open the **framework.h** file and comment out the following line of code. Save the file when you're done.

```
C++

#define WIN32_LEAN_AND_MEAN
```

2. Open the **MyDesktopWin32App.h** file and replace the contents of this file with the following code to reference necessary C++/WinRT header files. Save the file when you're done.

```
C++

#pragma once

#include "resource.h"
#include <winrt/Windows.Foundation.Collections.h>
#include <winrt/Windows.system.h>
#include <winrt/windows.ui.xaml.hosting.h>
#include <windows.ui.xaml.hosting.desktopwindowxamlsource.h>
#include <winrt/windows.ui.xaml.controls.h>
#include <winrt/Windows.ui.xaml.media.h>
#include <winrt/Windows.UI.Core.h>
#include <winrt/MyUWPApp.h>

using namespace winrt;
using namespace Windows::UI;
using namespace Windows::UI::Composition;
using namespace Windows::UI::Xaml::Hosting;
using namespace Windows::Foundation::Numerics;
using namespace Windows::UI::Xaml::Controls;
```

3. Open the **MyDesktopWin32App.cpp** file and add the following code to the `Global Variables:` section.

```
C++

winrt::MyUWPApp::App hostApp{ nullptr };
winrt::Windows::UI::Xaml::Hosting::DesktopWindowXamlSource
```

```
_desktopWindowXamlSource{ nullptr };
winrt::MyUWPApp::MyUserControl _myUserControl{ nullptr };
```

4. In the same file, add the following code to the `Forward declarations of functions included in this code module:` section.

```
C++

void AdjustLayout(HWND);
```

5. In the same file, add the following code immediately after the `TODO: Place code here.` comment in the `wWinMain` function.

```
C++

// TODO: Place code here.
winrt::init_apartment(winrt::apartment_type::single_threaded);
hostApp = winrt::MyUWPApp::App{};
_desktopWindowXamlSource =
winrt::Windows::UI::Xaml::Hosting::DesktopWindowXamlSource{};
```

6. In the same file, replace the default `InitInstance` function with the following code.

```
C++

BOOL InitInstance(HINSTANCE hInstance, int nCmdShow)
{
    hInst = hInstance; // Store instance handle in our global variable

    HWND hWnd = CreateWindowW(szWindowClass, szTitle,
WS_OVERLAPPEDWINDOW,
        CW_USEDEFAULT, 0, CW_USEDEFAULT, 0, nullptr, nullptr,
hInstance, nullptr);

    if (!hWnd)
    {
        return FALSE;
    }

    // Begin XAML Islands walkthrough code.
    if (_desktopWindowXamlSource != nullptr)
    {
        auto interop =
_desktopWindowXamlSource.as<IDesktopWindowXamlSourceNative>();
        check_hresult(interop->AttachToWindow(hWnd));
        HWND hWndXamlIsland = nullptr;
        interop->get_WindowHandle(&hWndXamlIsland);
        RECT windowRect;
        ::GetWindowRect(hWnd, &windowRect);
```

```
        ::SetWindowPos(hWndXamlIsland, NULL, 0, 0, windowRect.right -
windowRect.left, windowRect.bottom - windowRect.top, SWP_SHOWWINDOW);
        _myUserControl = winrt::MyUWPApp::MyUserControl();
        _desktopWindowXamlSource.Content(_myUserControl);
    }
    // End XAML Islands walkthrough code.

    ShowWindow(hWnd, nCmdShow);
    UpdateWindow(hWnd);

    return TRUE;
}
```

7. In the same file, add the following new function to the end of the file.

C++

```
void AdjustLayout(HWND hWnd)
{
    if (_desktopWindowXamlSource != nullptr)
    {
        auto interop =
_desktopWindowXamlSource.as<IDesktopWindowXamlSourceNative>();
        HWND xamlHostHwnd = NULL;
        check_hresult(interop->get_WindowHandle(&xamlHostHwnd));
        RECT windowRect;
        ::GetWindowRect(hWnd, &windowRect);
        ::SetWindowPos(xamlHostHwnd, NULL, 0, 0, windowRect.right -
windowRect.left, windowRect.bottom - windowRect.top, SWP_SHOWWINDOW);
    }
}
```

8. In the same file, locate the `WndProc` function. Replace the default `WM_DESTROY` handler in the switch statement with the following code.

C++

```
case WM_DESTROY:
    PostQuitMessage(0);
    if (_desktopWindowXamlSource != nullptr)
    {
        _desktopWindowXamlSource.Close();
        _desktopWindowXamlSource = nullptr;
    }
    break;
case WM_SIZE:
    AdjustLayout(hWnd);
    break;
```

9. Save the file.

10. Build the solution and confirm that it builds successfully.

Add a control from the WinUI 2 library to the custom control

Traditionally, WinRT XAML controls have been released as part of the Windows OS and made available to developers through the Windows SDK. The WinUI library is an alternative approach, where updated versions of WinRT XAML controls from the Windows SDK are distributed in a NuGet package that is not tied to Windows SDK releases. This library also includes new controls that aren't part of the Windows SDK and the default UWP platform.

This section demonstrates how to add a WinRT XAML control from the WinUI 2 library to your user control.

> **Note**
>
> Currently, XAML Islands only supports hosting controls from the WinUI 2 library. Support for hosting controls from the WinUI 3 library is coming in a later release.

1. In the **MyUWPApp** project, install the latest prerelease or release version of the Microsoft.UI.Xaml NuGet package.

    - If you chose to package the MyDesktopWin32App project using MSIX earlier in this walkthrough, you can install either the prerelease or release version of the Microsoft.UI.Xaml NugGet package. Packaged desktop apps can use either the prerelease or release version of this package.
    - If you chose not to package the **MyDesktopWin32App** project, you must install the prerelease version of the Microsoft.UI.Xaml NuGet package. Unpackaged desktop apps must use the prerelease version of this package.

2. In the pch.h file in this project, add the following `#include` statements and save your changes. These statements bring a required set of projection headers from the WinUI library into your project. This step is required for any C++/WinRT project that uses the WinUI library. For more information, see this article.

    C++

    ```
    #include "winrt/Microsoft.UI.Xaml.Automation.Peers.h"
    #include "winrt/Microsoft.UI.Xaml.Controls.Primitives.h"
    ```

```
#include "winrt/Microsoft.UI.Xaml.Media.h"
#include "winrt/Microsoft.UI.Xaml.XamlTypeInfo.h"
```

3. In the App.xaml file in the same project, add the following child element to the `<xaml:XamlApplication>` element and save your changes.

```
XML

<Application.Resources>
    <XamlControlsResources xmlns="using:Microsoft.UI.Xaml.Controls" />
</Application.Resources>
```

After adding this element, the contents of this file should now look similar to this.

```
XML

<Toolkit:XamlApplication
    x:Class="MyUWPApp.App"
    xmlns:Toolkit="using:Microsoft.Toolkit.Win32.UI.XamlHost"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:MyUWPApp">
    <Application.Resources>
        <XamlControlsResources
xmlns="using:Microsoft.UI.Xaml.Controls"/>
    </Application.Resources>
</Toolkit:XamlApplication>
```

4. In the same project, open the MyUserControl.xaml file and add the following namespace declaration to the `<UserControl>` element.

```
XML

xmlns:winui="using:Microsoft.UI.Xaml.Controls"
```

5. In the same file, add a `<winui:RatingControl />` element as a child of the `<StackPanel>` and save your changes. This element adds an instance of the RatingControl class from the WinUI library. After adding this element, the `<StackPanel>` should now look similar to this.

```
XML

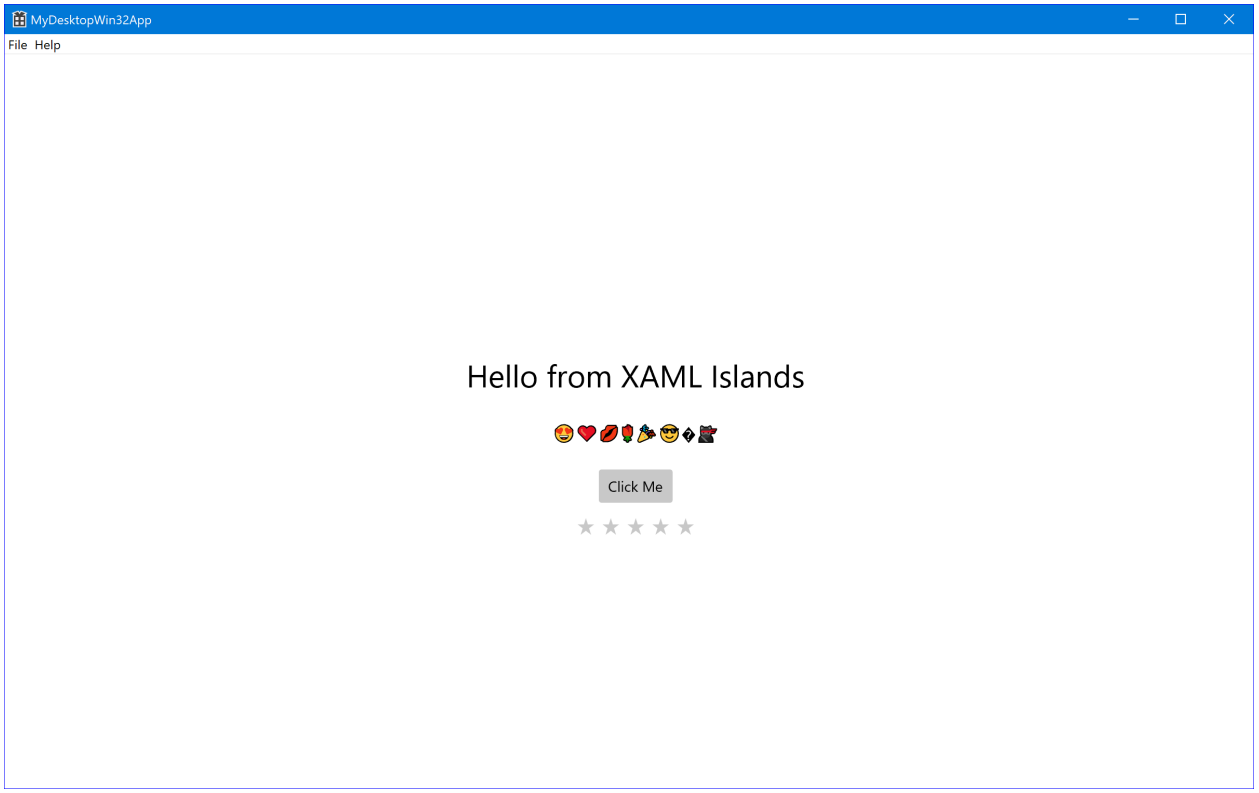
<StackPanel HorizontalAlignment="Center" Spacing="10"
            Padding="20" VerticalAlignment="Center">
    <TextBlock HorizontalAlignment="Center" TextWrapping="Wrap"
                   Text="Hello from XAML Islands" FontSize="30" />
```

```
    <TextBlock HorizontalAlignment="Center" Margin="15"
TextWrapping="Wrap"
                    Text="😍❤️🌶️🌹🎉😎🔷🏴" FontSize="16" />
    <Button HorizontalAlignment="Center"
            x:Name="Button" Click="ClickHandler">Click Me</Button>
    <winui:RatingControl />
</StackPanel>
```

6. Build the solution and confirm that it builds successfully.

Test the app

Run the solution and confirm that **MyDesktopWin32App** opens with the following window.



Next steps

Many desktop applications that host XAML Islands will need to handle additional scenarios in order to provide a smooth user experience. For example, desktop applications may need to handle keyboard input in XAML Islands, focus navigation between XAML Islands and other UI elements, and layout changes.

For more information about handling these scenarios and pointers to related code samples, see Advanced scenarios for XAML Islands in C++ desktop apps.

Advanced scenarios for XAML Islands in C++ desktop (Win32) apps

Article • 08/21/2024

> **Important**
>
> This topic uses or mentions types from the CommunityToolkit/Microsoft.Toolkit.Win32 GitHub repo. For important info about XAML Islands support, please see the XAML Islands Notice in that repo.

The host a standard UWP control and host a custom UWP control articles provide instructions and examples for hosting XAML Islands in a C++ desktop (Win32) app. However, the code examples in these articles do not handle many advanced scenarios that desktop applications may need to handle to provide a smooth user experience. This article provides guidance for some of these scenarios and pointers to related code samples.

Keyboard input

To properly handle keyboard input for each XAML Island, your application must pass all Windows messages to the UWP XAML framework so that certain messages can be processed correctly. To do this, in some place in your application that can access the message loop, cast the **DesktopWindowXamlSource** object for each XAML Island to an **IDesktopWindowXamlSourceNative2** COM interface. Then, call the **PreTranslateMessage** method of this interface and pass in the current message.

- **C++ desktop (Win32)**:: The app can call **PreTranslateMessage** directly in its main message loop. For an example, see the XamlBridge.cpp file.
- **WPF:** The app can call **PreTranslateMessage** from the event handler for the ComponentDispatcher.ThreadFilterMessage event. For an example, see the WindowsXamlHostBase.Focus.cs file in the Windows Community Toolkit.
- **Windows Forms:** The app can call **PreTranslateMessage** from an override for the Control.PreprocessMessage method. For an example, see the WindowsXamlHostBase.KeyboardFocus.cs file in the Windows Community Toolkit.

Keyboard focus navigation

When the user navigates through the UI elements in your application using the keyboard (for example, by pressing **Tab** or direction/arrow key), you'll need to programmatically move focus into and out of the **DesktopWindowXamlSource** object. When the user's keyboard navigation reaches the **DesktopWindowXamlSource**, move focus into the first Windows.UI.Xaml.UIElement object in the navigation order for your UI, continue to move focus to the following **Windows.UI.Xaml.UIElement** objects as the user cycles through the elements, and then move focus back out of the **DesktopWindowXamlSource** and into the parent UI element.

The UWP XAML hosting API provides several types and members to help you accomplish these tasks.

- When the keyboard navigation enters your **DesktopWindowXamlSource**, the GotFocus event is raised. Handle this event and programmatically move focus to the first hosted **Windows.UI.Xaml.UIElement** by using the NavigateFocus method.
- When the user is on the last focusable element in your **DesktopWindowXamlSource** and presses the **Tab** key or an arrow key, the TakeFocusRequested event is raised. Handle this event and programmatically move focus to the next focusable element in the host application. For example, in a WPF application where the **DesktopWindowXamlSource** is hosted in a System.Windows.Interop.HwndHost, you can use the MoveFocus method to transfer focus to the next focusable element in the host application.

For examples that demonstrate how to do this in the context of a working sample application, see the following code files:

- **C++ desktop (Win32)**: See the XamlBridge.cpp file.
- **WPF:** See the WindowsXamlHostBase.Focus.cs file in the Windows Community Toolkit.
- **Windows Forms:** See the WindowsXamlHostBase.KeyboardFocus.cs file in the Windows Community Toolkit.

Handle layout changes

When the user changes the size of the parent UI element, you'll need to handle any necessary layout changes to make sure your UWP controls display as you expect. Here are some important scenarios to consider.

- In a C++ desktop application, when your application handles the WM_SIZE message it can reposition the hosted XAML Island by using the SetWindowPos function. For an example, see the SampleApp.cpp code file.

- When the parent UI element needs to get the size of the rectangular area needed to fit the **Windows.UI.Xaml.UIElement** that you are hosting on the **DesktopWindowXamlSource**, call the Measure method of the **Windows.UI.Xaml.UIElement**. For example:

  - In a WPF application you might do this from the MeasureOverride method of the HwndHost that hosts the **DesktopWindowXamlSource**. For an example, see the WindowsXamlHostBase.Layout.cs file in the Windows Community Toolkit.

  - In a Windows Forms application you might do this from the GetPreferredSize method of the Control that hosts the **DesktopWindowXamlSource**. For an example, see the WindowsXamlHostBase.Layout.cs file in the Windows Community Toolkit.

- When the size of the parent UI element changes, call the Arrange method of the root **Windows.UI.Xaml.UIElement** that you are hosting on the **DesktopWindowXamlSource**. For example:

  - In a WPF application you might do this from the ArrangeOverride method of the HwndHost object that hosts the **DesktopWindowXamlSource**. For an example, see the WindowsXamlHost.Layout.cs file in the Windows Community Toolkit.

  - In a Windows Forms application you might do this from the handler for the SizeChanged event of the Control that hosts the **DesktopWindowXamlSource**. For an example, see the WindowsXamlHost.Layout.cs file in the Windows Community Toolkit.

Handle DPI changes

The UWP XAML framework handles DPI changes for hosted UWP controls automatically (for example, when the user drags the window between monitors with different screen DPI). For the best experience, we recommend that your Windows Forms, WPF, or C++ desktop application is configured to be per-monitor DPI aware.

To configure your application to be per-monitor DPI aware, add a side-by-side assembly manifest to your project and set the **<dpiAwareness>** element to **PerMonitorV2**. For more information about this value, see the description for DPI_AWARENESS_CONTEXT_PER_MONITOR_AWARE_V2.

XML

```xml
<?xml version="1.0" encoding="UTF-8" standalone="yes"?>
<assembly xmlns="urn:schemas-microsoft-com:asm.v1" manifestVersion="1.0">
    <application xmlns="urn:schemas-microsoft-com:asm.v3">
        <windowsSettings>
            <dpiAwareness
xmlns="http://schemas.microsoft.com/SMI/2016/WindowsSettings">PerMonitorV2</
dpiAwareness>
        </windowsSettings>
    </application>
</assembly>
```

Tutorial: Modernize a WPF app

Article • 05/13/2022

There are many ways to modernize existing desktop apps by integrating the latest Windows features into the existing source code instead of rewriting the apps from scratch. In this tutorial we'll explore several ways to modernize an existing WPF line-of-business app by using these features:

- .NET Core 3
- UWP XAML controls with XAML Islands
- Adaptive Cards and Windows notifications
- MSIX deployment

This tutorial requires the following development skills:

- Experience in developing Windows desktop apps with WPF.
- Basic knowledge of C# and XAML.
- Basic knowledge of UWP.

Overview

This tutorial provides the code for a simple WPF line-of-business app named Contoso Expenses. In the fictional scenario of the tutorial, Contoso Expenses is an internal app used by managers of Contoso Corporation to keep track of the expenses submitted by their reports. The managers are now equipped with touch-enabled devices, and they would like to use the Contoso Expenses app without a mouse or keyboard. Unfortunately, the current version of the app isn't touch friendly.

Contoso wants to modernize this app with new Windows features to enable employees to create expenses reports more efficiently. Many of the features could be easily implemented by building a new UWP app. However, the existing app is complex and is the result of many years of development by different teams. As such, rewriting it from scratch with a new technology isn't an option. The team is looking for the best approach to add new features into the existing codebase.

At the beginning of the tutorial, Contoso Expenses targets the .NET Framework 4.7.2 and uses the following 3rd party libraries:

- MVVM Light, a basic implementation for the MVVM pattern.
- Unity, a dependency injection container.
- LiteDb, an embedded NoSQL solution to store the data.

- Bogus, a tool to generate fake data.

In the tutorial, you'll enhance Contoso Expenses with new Windows features:

- Migrate an existing WPF app to .NET Core 3.0. This will open up new and important scenarios in the future.
- Use XAML Islands to host the **InkCanvas** and **MapControl** wrapped controls provided by the Windows Community Toolkit.
- Use XAML Islands to host any standard UWP XAML control (in this case, a **CalendarView**).
- Integrate Adaptive Cards and Windows notifications into the app.
- Package the app with MSIX and set up a CI/CD pipeline on Azure DevOps so that you can automatically deliver new versions of the app to testers and users as soon as it is available.

Prerequisites

To perform this tutorial, your development computer must have these prerequisites installed:

- Windows 10, version 1903 (build 18362) or a later version.
- Visual Studio 2019 .
- .NET Core 3 SDK (install the latest version).

Make sure you install the following workloads and optional features with Visual Studio 2019:

- .NET Desktop development
- Universal Windows Platform development
- Windows SDK (10.0.18362.0 or later)

Get the Contoso Expenses sample app

Before you begin the tutorial, download the source code for the Contoso Expenses app and make sure you can build the code in Visual Studio.

1. Download the app source code from the **Releases** tab of the AppConsult WinAppsModernization workshop repository . The direct link is https://github.com/microsoft/AppConsult-WinAppsModernizationWorkshop/releases.
2. Open the zip file and extract all the content to the root of your **C:** drive. It will create a folder named **C:\WinAppsModernizationWorkshop**.

3. Open Visual Studio 2019 and double click on the **C:\WinAppsModernizationWorkshop\Lab\Exercise1\01-Start\ContosoExpenses\ContosoExpenses.sln** file to open the solution.
4. Verify that you can build, run, and debug the Contoso Expenses WPF project by pressing the **Start** button or CTRL + F5.

Get started

After you have the source code for the Contoso Expenses sample app and you can confirm that you can build it in Visual Studio, you're ready to start the tutorial:

- Part 1: Migrate the Contoso Expenses app to .NET Core 3
- Part 2: Add a UWP InkCanvas control using XAML Islands
- Part 3: Add a UWP CalendarView control using XAML Islands
- Part 4: Add Windows 10 user activities and notifications
- Part 5: Package and deploy with MSIX

Important concepts

The following sections provide background for some of the key concepts discussed in this tutorial. If you're already familiar with these concepts, you can skip this section.

Universal Windows Platform (UWP)

In Windows 8, Microsoft introduced a new API set as part of the Windows Runtime (WinRT). Unlike the .NET Framework, WinRT is a native layer of APIs which are exposed directly to apps. WinRT also introduced language projections, which are layers added on top of the runtime to allow developers to interact with it using languages such as C# and JavaScript in addition to C++. Projections enable developers to build apps on top of WinRT that leverage the same C# and XAML knowledge they acquired in building apps with the .NET Framework.

In Windows 10, Microsoft introduced the Universal Windows Platform (UWP), which is built on top of WinRT. The most important feature of UWP is that it offers a common set of APIs across every device platform: no matter if the app is running on a desktop, on an Xbox One or on a HoloLens, you're able to use the same APIs.

Going forward, most new Windows features are exposed via WinRT APIs, including features such as Timeline, Project Rome, and Windows Hello.

MSIX packaging

MSIX is the modern packaging model for Windows apps. MSIX supports UWP apps as well as desktop apps building using technologies such as Win32, WPF, Windows Forms, Java, Electron, and more. When you package a desktop app in an MSIX package, you can publish your app to the Microsoft Store. Your desktop app also get package identity when it is installed, which enables your desktop app to use a broader set of WinRT APIs.

For more information, see these articles:

- Package desktop applications
- Behind the scenes of your packaged desktop application

XAML Islands

Starting in Windows 10, version 1903, you can host UWP controls in non-UWP desktop apps using a feature called *XAML Islands*. This feature enables you to enhance the look, feel, and functionality of your existing desktop apps with the latest Windows UI features that are only available via UWP controls. This means that you can use UWP features such as Windows Ink and controls that support the Fluent Design System in your existing WPF, Windows Forms, and C++ Win32 apps.

For more information, see UWP controls in desktop applications (XAML Islands). This tutorial guides you through the process of using two different types of XAML Island controls:

- The InkCanvas and MapControl in the Windows Community Toolkit. These WPF controls wrap the interface and functionality of the corresponding UWP controls and can be used like any other WPF control in the Visual Studio designer.
- The UWP Calendar view control. This is a standard UWP control that you will host by using the WindowsXamlHost control in the Windows Community Toolkit.

.NET Core 3

.NET Core is an open-source framework that implements a cross-platform, lightweight and easily extensible version of the full .NET Framework. Compared to the full .NET Framework, .NET Core startup time is much faster and many of the APIs have been optimized.

Through its first several releases, the focus of .NET Core was for supporting web or back-end apps. With .NET Core, you can easily build scalable web apps or APIs that can be hosted on Windows, Linux, or in micro-service architectures like Docker containers.

.NET Core 3 is latest release of .NET Core. The highlight of this release is support for Windows desktop apps, including Windows Forms and WPF apps. You can run new and existing Windows desktop apps on .NET Core 3 and enjoy all the benefits that .NET Core has to offer. UWP controls that are hosted in XAML Islands can also be used in Windows Forms and WPF apps that target .NET Core 3.

> **Note**
>
> WPF and Windows Forms are not becoming cross-platform, and you cannot run a WPF or Windows Forms on Linux and MacOS. The UI components of WPF and Windows Forms still have a dependency on the Windows rendering system.

For more information, see What's new in .NET Core 3.0.

Part 1: Migrate the Contoso Expenses app to .NET Core 3

Article • 10/16/2021

This is the first part of a tutorial that demonstrates how to modernize a sample WPF desktop app named Contoso Expenses. For an overview of the tutorial, prerequisites, and instructions for downloading the sample app, see Tutorial: Modernize a WPF app.

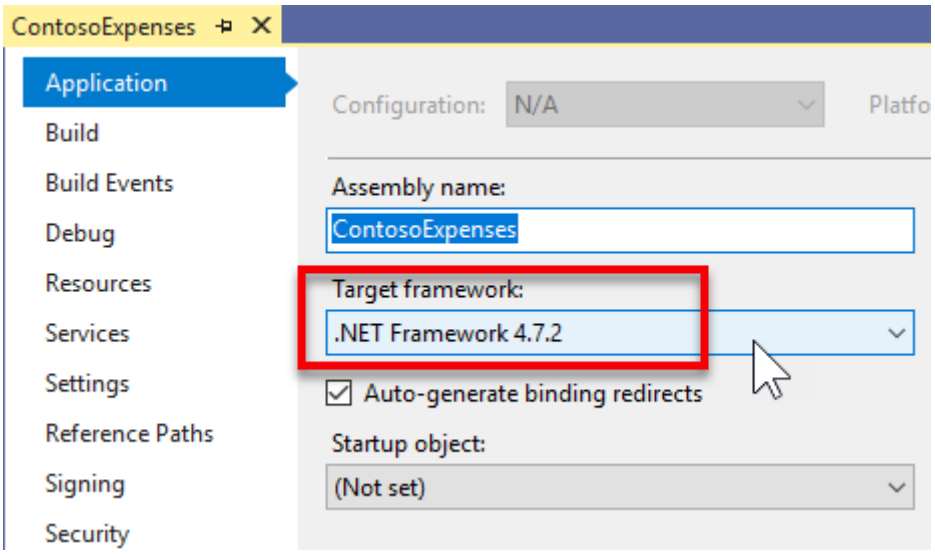
In this part of the tutorial, you will migrate the entire Contoso Expenses app from the .NET Framework 4.7.2 to .NET Core 3. Before you start this part of the tutorial, make sure you open and build the ContosoExpenses sample in Visual Studio 2019.

> **Note**
>
> For more information about migrating a WPF application from the .NET Framework to .NET Core 3, see this blog series.

Migrate the ContosoExpenses project to .NET Core 3

In this section, you'll migrate the ContosoExpenses project in the Contoso Expenses app to .NET Core 3. You'll do this by creating a new project file that contains the same files as the existing ContosoExpenses project but targets .NET Core 3 instead of the .NET Framework 4.7.2. This enables you to maintain a single solution with both .NET Framework and .NET Core versions of the app.

1. Verify that the ContosoExpenses project currently targets the .NET Framework 4.7.2. In Solution Explorer, right-click the **ContosoExpenses** project, choose **Properties**, and confirm that the **Target framework** property on the **Application** tab is set to the .NET Framework 4.7.2.



2. In Windows Explorer, navigate to the **C:\WinAppsModernizationWorkshop\Lab\Exercise1\01-Start\ContosoExpenses** folder and create a new text file named **ContosoExpenses.Core.csproj**.

3. Right click on the file, choose **Open with**, and then open it in a text editor of your choice, such as Notepad, Visual Studio Code or Visual Studio.

4. Copy the following text to the file and save it.

```xml
<Project Sdk="Microsoft.NET.Sdk.WindowsDesktop">

  <PropertyGroup>
    <OutputType>WinExe</OutputType>
    <TargetFramework>netcoreapp3.0</TargetFramework>
    <UseWPF>true</UseWPF>
 </PropertyGroup>

</Project>
```

5. Close the file and return to the **ContosoExpenses** solution in Visual Studio.

6. Right-click the **ContosoExpenses** solution and choose **Add -> Existing Project**. Select the **ContosoExpenses.Core.csproj** file you just created in the `C:\WinAppsModernizationWorkshop\Lab\Exercise1\01-Start\ContosoExpenses` folder to add it to the solution.

The **ContosoExpenses.Core.csproj** includes the following elements:

- The **Project** element specifies an SDK version of **Microsoft.NET.Sdk.WindowsDesktop**. This refers to .NET applications for Windows Desktop, and it includes components for WPF and Windows Forms apps.

- The **PropertyGroup** element contains child elements that indicate the project output is an executable (not a DLL), targets .NET Core 3, and uses WPF. For a Windows Forms app, you would use a **UseWinForms** element instead of the **UseWPF** element.

> **Note**
>
> When working with the .csproj format introduced with .NET Core 3.0, all the files in the same folder as the .csproj are considered part of the project. Therefore, you don't have to specify every file included in the project. You must specify only those files for which you want to define a custom build action or that you want to exclude.

Migrate the ContosoExpenses.Data project to .NET Standard

The **ContosoExpenses** solution includes a **ContosoExpenses.Data** class library that contains models and interfaces for services and targets .NET 4.7.2. .NET Core 3.0 apps can use .NET Framework libraries, as long as they don't use APIs which aren't available in .NET Core. However, the best modernization path is to move your libraries to .NET Standard. This will make sure that your library is fully supported by your .NET Core 3.0 app. Additionally, you can reuse the library also with other platforms, such as web (through ASP.NET Core).

To migrate the **ContosoExpenses.Data** project to .NET Standard:

1. In Visual Studio, right-click the **ContosoExpenses.Data** project and choose **Unload Project**. Right-click the project again and then choose **Edit ContosoExpenses.Data.csproj**.

2. Delete the entire contents of the project file.

3. Copy and paste the following XML and save the file.

   XML

   ```xml
   <Project Sdk="Microsoft.NET.Sdk">

     <PropertyGroup>
       <TargetFramework>netstandard2.0</TargetFramework>
     </PropertyGroup>
   ```

```
</Project>
```

4. Right-click the **ContosoExpenses.Data** project and choose **Reload Project**.

Configure NuGet packages and dependencies

When you migrated the **ContosoExpenses.Core** and **ContosoExpenses.Data** projects in the previous sections, you removed the NuGet package references from the projects. In this section, you'll add these references back.

To configure NuGet packages for the **ContosoExpenses.Data** project:

1. In the **ContosoExpenses.Data** project, expand the **Dependencies** node. Note that the **NuGet** section is missing.

   If you open the **Packages.config** in the **Solution Explorer** you will find the 'old' references of the NuGet packages used the project when it was using the full .NET Framework.

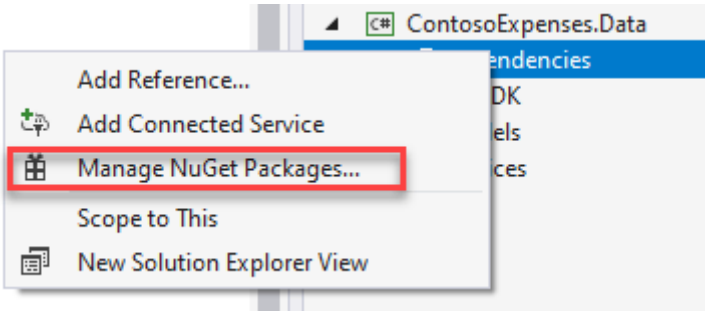
   Here is the content of the **Packages.config** file. You will notice that all the NuGet Packages target the Full .NET Framework 4.7.2:

   XML

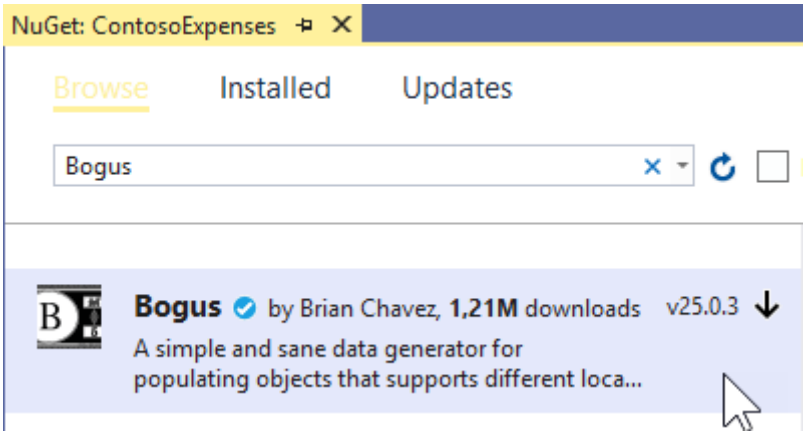
```
<?xml version="1.0" encoding="utf-8"?>
<packages>
  <package id="Bogus" version="26.0.2" targetFramework="net472" />
  <package id="LiteDB" version="4.1.4" targetFramework="net472" />
</packages>
```

2. In the **ContosoExpenses.Data** project, delete the **Packages.config** file.

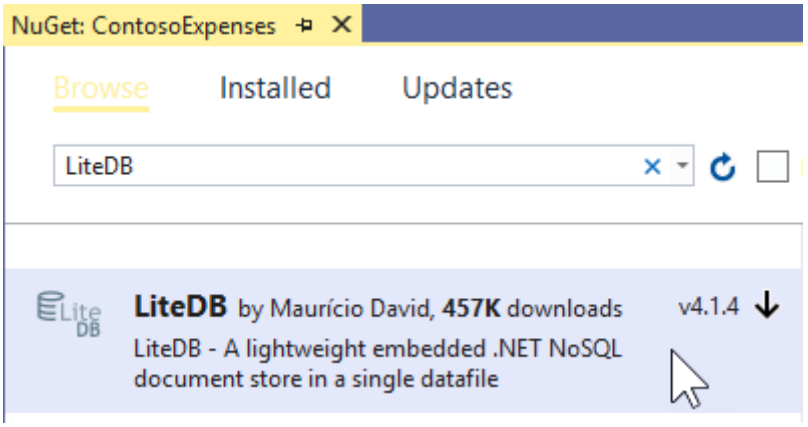
3. In the **ContosoExpenses.Data** project, right-click the **Dependencies** node and choose **Manage NuGet Packages**.



5. In the **NuGet Package Manager** window, click **Browse**. Search for the `Bogus` package and install the latest stable version.



6. Search for the `LiteDB` package and install the latest stable version.



You may be wondering where these list of NuGet packages is stored, since the project no longer has a packages.config file. The referenced NuGet packages are stored directly in the .csproj file. You can check this by viewing the contents of the **ContosoExpenses.Data.csproj** project file in a text editor. You will find the following lines added at the end of the file:

```
XML
```

```
<ItemGroup>
   <PackageReference Include="Bogus" Version="26.0.2" />
   <PackageReference Include="LiteDB" Version="4.1.4" />
</ItemGroup>
```

> **Note**
>
> You may also notice that you're installing the same packages for this .NET Core 3 project as the ones used by .NET Framework 4.7.2 projects. NuGet packages supports multi-targeting. Library authors can include different versions of a library in the same package, compiled for different architectures and platforms. These packages support the full .NET Framework as well as .NET Standard 2.0, which is compatible with .NET Core 3 projects. For more info about the differences .NET Framework, .NET Core and .NET Standard, see .NET Standard.

To configure NuGet packages for the **ContosoExpenses.Core** project:

1. In the **ContosoExpenses.Core** project, open the **packages.config** file. Notice that it currently contains the following references that target the .NET Framework 4.7.2.

   XML

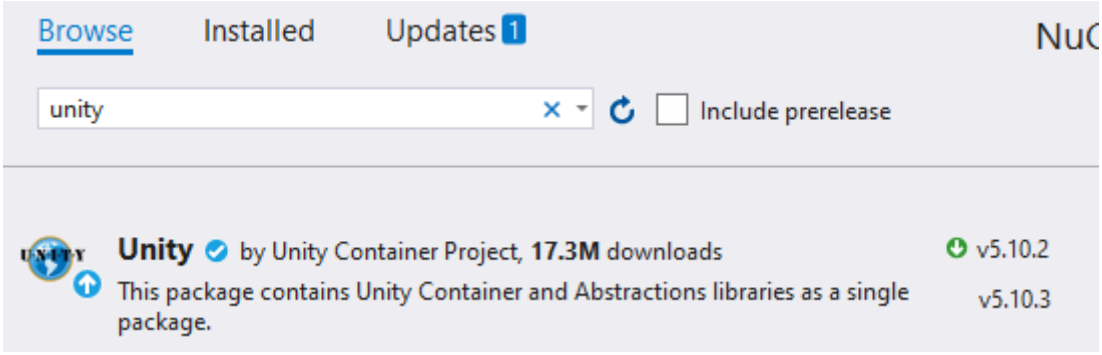
   ```
   <?xml version="1.0" encoding="utf-8"?>
   <packages>
     <package id="CommonServiceLocator" version="2.0.2"
   targetFramework="net472" />
     <package id="MvvmLightLibs" version="5.4.1.1"
   targetFramework="net472" />
     <package id="System.Runtime.CompilerServices.Unsafe" version="4.5.2"
   targetFramework="net472" />
     <package id="Unity" version="5.10.2" targetFramework="net472" />
   </packages>
   ```

   In the following steps you'll .NET Standard versions of the `MvvmLightLibs` and `Unity` packages. The other two are dependencies automatically downloaded by NuGet when you install these two libraries.

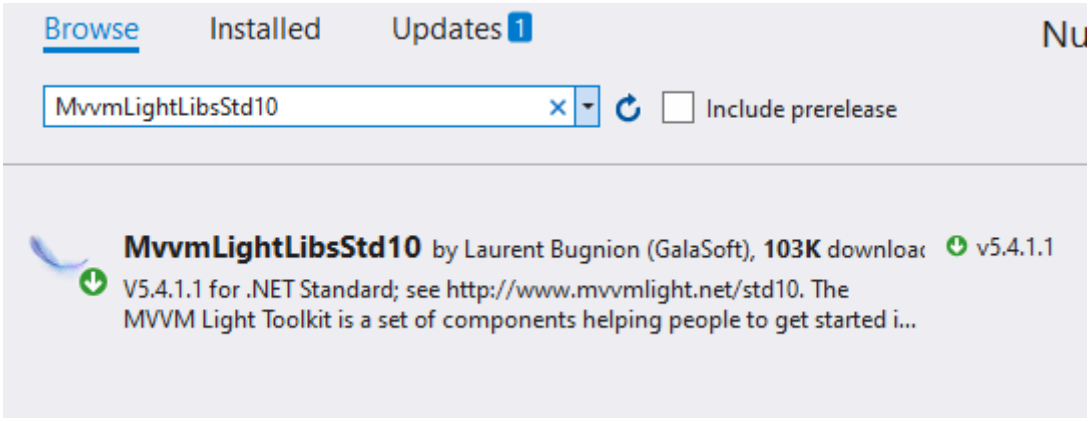
2. In the **ContosoExpenses.Core** project, delete the **Packages.config** file.

3. Right-click the **ContosoExpenses.Core** project and choose **Manage NuGet Packages**.

4. In the **NuGet Package Manager** window, click **Browse**. Search for the `Unity` package and install the latest stable version.

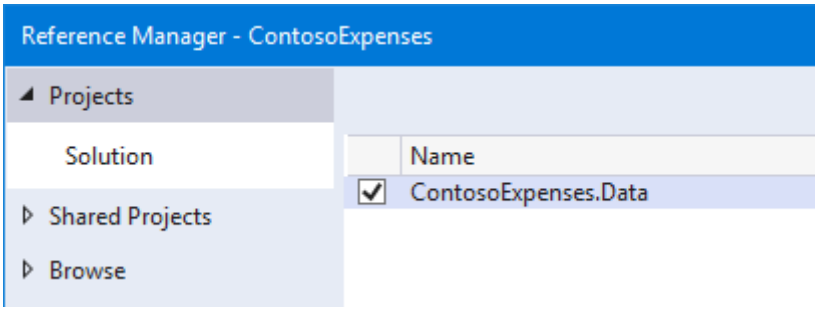


5. Search for the `MvvmLightLibsStd10` package and install the latest stable version. This is the .NET Standard version of the `MvvmLightLibs` package. For this package, the author chose to package the .NET Standard version of the library in a separate package than the .NET Framework version.



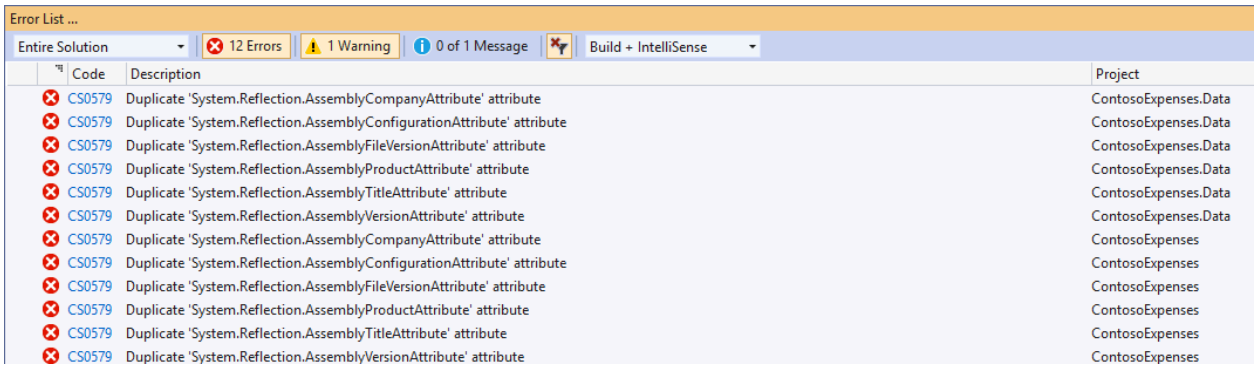
6. In the **ContosoExpenses.Core** project, right-click the **Dependencies** node and choose **Add Reference**.

7. In the **Projects** > **Solution** category, select **ContosoExpenses.Data** and click **OK**.



Disable auto-generated assembly attributes

At this point in the migration process, if you try to build the **ContosoExpenses.Core** project you'll see some errors.



This problem is happening because the new .csproj format introduced with .NET Core 3.0 stores the assembly info in the project file rather than the **AssemblyInfo.cs** file. To fix these errors, disable this behavior and let the project continue to use the **AssemblyInfo.cs** file.

1. In Visual Studio, right-click the **ContosoExpenses.Core** project and choose **Unload Project**. Right-click the project again and then choose **Edit ContosoExpenses.Core.csproj**.

2. Add the following element in the **PropertyGroup** section and save the file.

   XML

   ```
   <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
   ```

   After adding this element, the **PropertyGroup** section should now look like this:

   XML

   ```
   <PropertyGroup>
     <OutputType>WinExe</OutputType>
     <TargetFramework>netcoreapp3.0</TargetFramework>
     <UseWPF>true</UseWPF>
     <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
   </PropertyGroup>
   ```

3. Right-click the **ContosoExpenses.Core** project and choose **Reload Project**.

4. Right-click the **ContosoExpenses.Data** project and choose **Unload Project**. Right-click the project again and then choose **Edit ContosoExpenses.Data.csproj**.

5. Add the same entry in the **PropertyGroup** section and save the file.

   XML

   ```
   <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
   ```

After adding this element, the **PropertyGroup** section should now look like this:

```
XML

<PropertyGroup>
  <TargetFramework>netstandard2.0</TargetFramework>
  <GenerateAssemblyInfo>false</GenerateAssemblyInfo>
</PropertyGroup>
```

6. Right-click the **ContosoExpenses.Data** project and choose **Reload Project**.

Add the Windows Compatibility Pack

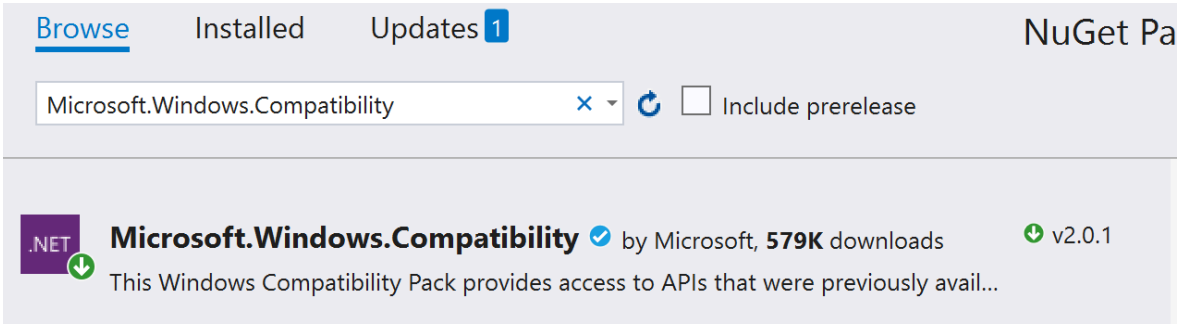
If you now try to compile the **ContosoExpenses.Core** and **ContosoExpenses.Data** projects, you'll see that the previous errors are now fixed but there are still some errors in the **ContosoExpenses.Data** library similar to these.

`Services\RegistryService.cs(9,26,9,34): error CS0103: The name 'Registry' does not exist in the current context` `Services\RegistryService.cs(12,26,12,34): error CS0103: The name 'Registry' does not exist in the current context` `Services\RegistryService.cs(12,97,12,123): error CS0103: The name 'RegistryKeyPermissionCheck' does not exist in the current context`

These errors are a result of converting the **ContosoExpenses.Data** project from a .NET Framework library (which is specific for Windows) to a .NET Standard library, which can run on multiple platforms including Linux, Android, iOS, and more. The **ContosoExpenses.Data** project contains a class called **RegistryService**, which interacts with the registry, a Windows-only concept.

To resolve these errors, install the Windows Compatibility NuGet package. This package provides support for many Windows-specific APIs to be used in a .NET Standard library. The library will no longer be cross-platform after using this package, but it will still target .NET Standard.

1. Right-click on the **ContosoExpenses.Data** project.
2. Choose **Manage NuGet Packages**.
3. In the **NuGet Package Manager** window, click **Browse**. Search for the `Microsoft.Windows.Compatibility` package and install the latest stable version.



4. Now try again to compile the project, by right clicking on the **ContosoExpenses.Data** project and choosing **Build**.

This time the build process will complete without errors.

Test and debug the migration

Now that the projects are building successfully, you are ready to run and test the app to see if there are any runtime errors.

1. Right-click the **ContosoExpenses.Core** project and choose **Set as Startup Project**.

2. Press F5 to start the **ContosoExpenses.Core** project in the debugger. You'll see an exception similar to the following.

   This exception is being raised because when you deleted the content from the .csproj file at the beginning of the migration, you removed the information about the **Build action** for the image files. The following steps fix this issue.

3. Stop the debugger.

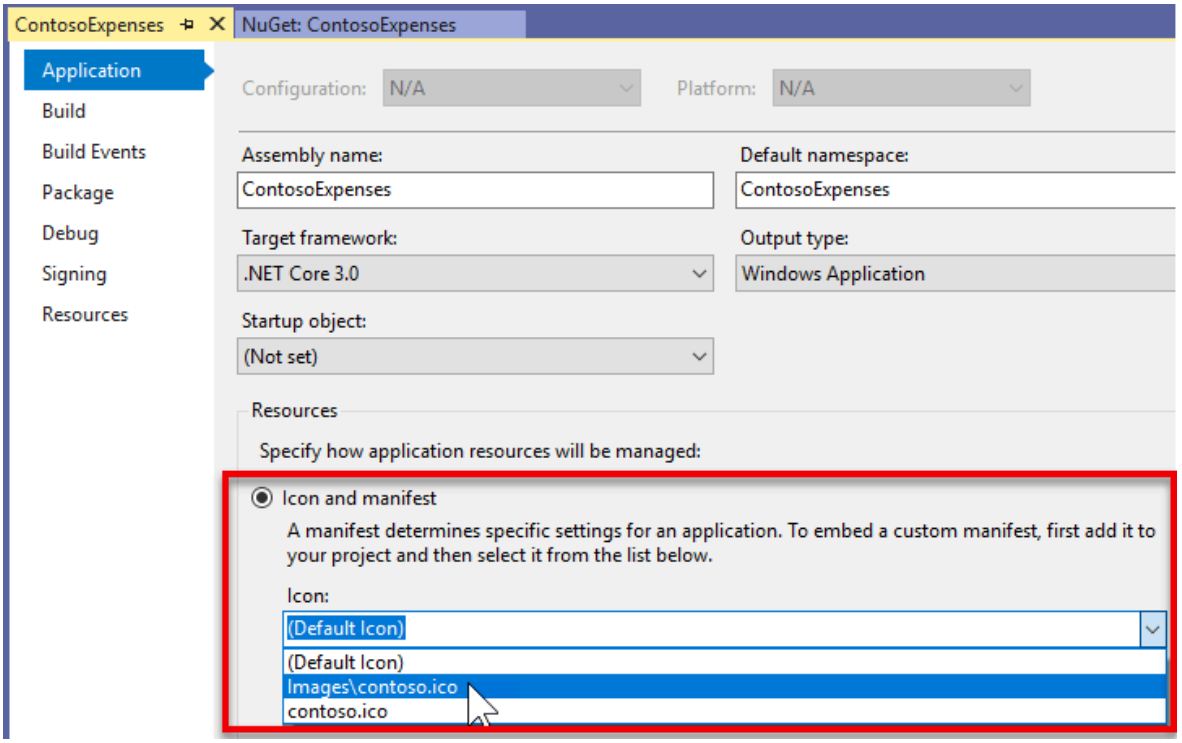
4. Right-click the **ContosoExpenses.Core** project and choose **Unload Project**. Right-click the project again and then choose **Edit ContosoExpenses.Core.csproj**.

5. Before the closing **Project** element, add the following entry:

```xml
<ItemGroup>
  <Content Include="Images/*">
    <CopyToOutputDirectory>PreserveNewest</CopyToOutputDirectory>
  </Content>
</ItemGroup>
```

6. Right-click the **ContosoExpenses.Core** project and choose **Reload Project**.

7. To assign the Contoso.ico to the app, right-click the **ContosoExpenses.Core** project and choose **Properties**. In the opened page, click drop-down under **Icon** and select `Images\contoso.ico`.



8. Click **Save**.

9. Press F5 to start the **ContosoExpenses.Core** project in the debugger. Confirm that the app now runs.

Next steps

At this point in the tutorial, you have successfully migrated the Contoso Expenses app to .NET Core 3. You are now ready for Part 2: Add a UWP InkCanvas control using XAML Islands.

> ⓘ Note

If you have a high resolution screen, you may notice that the app looks very small. You'll address this problem in the next step of the tutorial.

Part 2: Add a UWP InkCanvas control using XAML Islands

Article • 10/16/2021

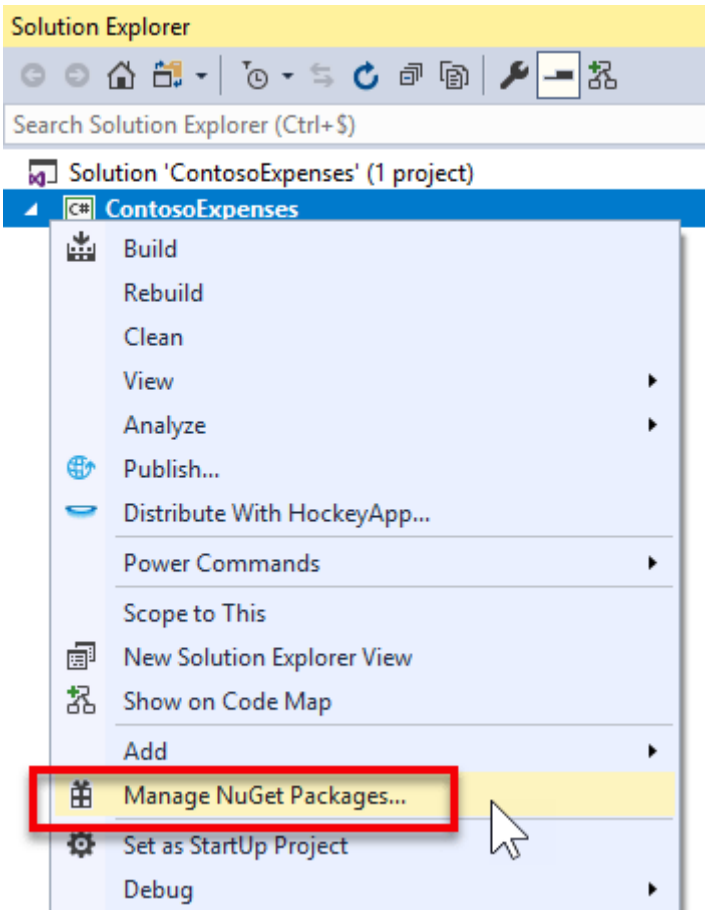
This is the second part of a tutorial that demonstrates how to modernize a sample WPF desktop app named Contoso Expenses. For an overview of the tutorial, prerequisites, and instructions for downloading the sample app, see Tutorial: Modernize a WPF app. This article assumes you have already completed part 1.

In the fictional scenario of this tutorial, the Contoso development team wants to add support for digital signatures to the Contoso Expenses app. The UWP **InkCanvas** control is a great option for this scenario, because it supports digital ink and AI-powered features like the capability to recognize text and shapes. To do this, you will use the InkCanvas wrapped UWP control available in the Windows Community Toolkit. This control wraps the interface and functionality of the UWP **InkCanvas** control for use in a WPF app. For more details about wrapped UWP controls, see Host UWP XAML controls in desktop apps (XAML Islands).

Configure the project to use XAML Islands

Before you can add an **InkCanvas** control to the Contoso Expenses app, you first need to configure the project to support UWP XAML Islands.

1. In Visual Studio 2019, right-click on the **ContosoExpenses.Core** project in **Solution Explorer** and choose **Manage NuGet Packages**.



2. In the **NuGet Package Manager** window, click **Browse**. Search for the `Microsoft.Toolkit.Wpf.UI.Controls` package and install version 6.0.0 or a later version.

> ⓘ Note
>
> This package contains all the necessary infrastructure for hosting UWP XAML Islands in a WPF app, including the **InkCanvas** wrapped UWP control. A similar package named `Microsoft.Toolkit.Forms.UI.Controls` is available for Windows Forms apps.

3. Right-click **ContosoExpenses.Core** project in **Solution Explorer** and choose **Add -> New item**.

4. Select **Application Manifest File**, name it **app.manifest**, and click **Add**. For more information about application manifests, see this article.

5. In the manifest file, uncomment the following `<supportedOS>` element for Windows 10.

```
XML
```

```
<!-- Windows 10 -->
<supportedOS Id="{8e0f7a12-bfb3-4fe8-b9a5-48fd50a15a9a}" />
```

6. In the manifest file, locate the following commented `<application>` element.

```
XML

<!--
<application xmlns="urn:schemas-microsoft-com:asm.v3">
  <windowsSettings>
    <dpiAware
xmlns="http://schemas.microsoft.com/SMI/2005/WindowsSettings">true</dpi
Aware>
  </windowsSettings>
</application>
-->
```

7. Delete this section and replace it with the following XML. This configures the app to be DPI aware and better handle different scaling factors supported by Windows 10.

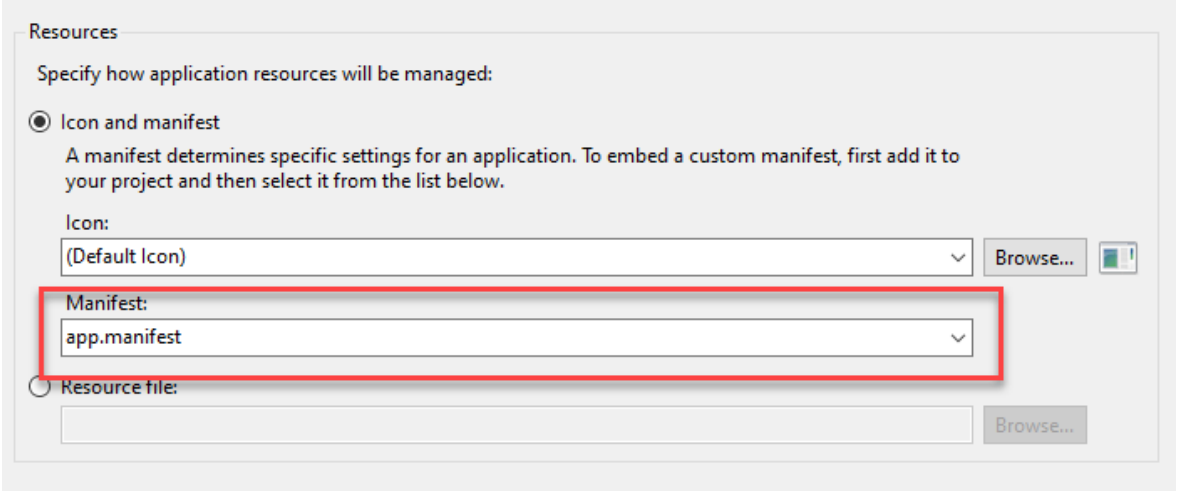
```
XML

<application xmlns="urn:schemas-microsoft-com:asm.v3">
  <windowsSettings>
      <dpiAware
xmlns="http://schemas.microsoft.com/SMI/2005/WindowsSettings">true/PM</
dpiAware>
      <dpiAwareness
xmlns="http://schemas.microsoft.com/SMI/2016/WindowsSettings">PerMonito
rV2, PerMonitor</dpiAwareness>
  </windowsSettings>
</application>
```

8. Save and close the `app.manifest` file.

9. In **Solution Explorer**, right-click the **ContosoExpenses.Core** project and choose **Properties**.

10. In the **Resources** section of the **Application** tab, make sure the **Manifest** dropdown is set to **app.manifest**.



11. Save the changes to the project properties.

Add an InkCanvas control to the app

Now that you have configured your project to use UWP XAML Islands, you are now ready to add an InkCanvas wrapped UWP control to the app.

1. In **Solution Explorer**, expand the **Views** folder of the **ContosoExpenses.Core** project and double-click the **ExpenseDetail.xaml** file.

2. In the **Window** element near the top of the XAML file, add the following attribute. This references the XAML namespace for the InkCanvas wrapped UWP control.

```
XML

xmlns:toolkit="clr-
namespace:Microsoft.Toolkit.Wpf.UI.Controls;assembly=Microsoft.Toolkit.
Wpf.UI.Controls"
```

After adding this attribute, the **Window** element should now look like this.

```
XML

<Window x:Class="ContosoExpenses.Views.ExpenseDetail"

xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-
compatibility/2006"
        xmlns:toolkit="clr-
namespace:Microsoft.Toolkit.Wpf.UI.Controls;assembly=Microsoft.Toolkit.
Wpf.UI.Controls"
        xmlns:converters="clr-namespace:ContosoExpenses.Converters"
        DataContext="{Binding Source={StaticResource ViewModelLocator},
```

```
Path=ExpensesDetailViewModel}"
        xmlns:local="clr-namespace:ContosoExpenses"
        mc:Ignorable="d"
        Title="Expense Detail" Height="500" Width="800"
        Background="{StaticResource HorizontalBackground}">
```

3. In the **ExpenseDetail.xaml** file, locate the closing `</Grid>` tag that immediately precedes the `<!-- Chart -->` comment. Add the following XAML just before the closing `</Grid>` tag. This XAML adds an **InkCanvas** control (prefixed by the **toolkit** keyword you defined earlier as a namespace) and a simple **TextBlock** that acts as a header for the control.

XML

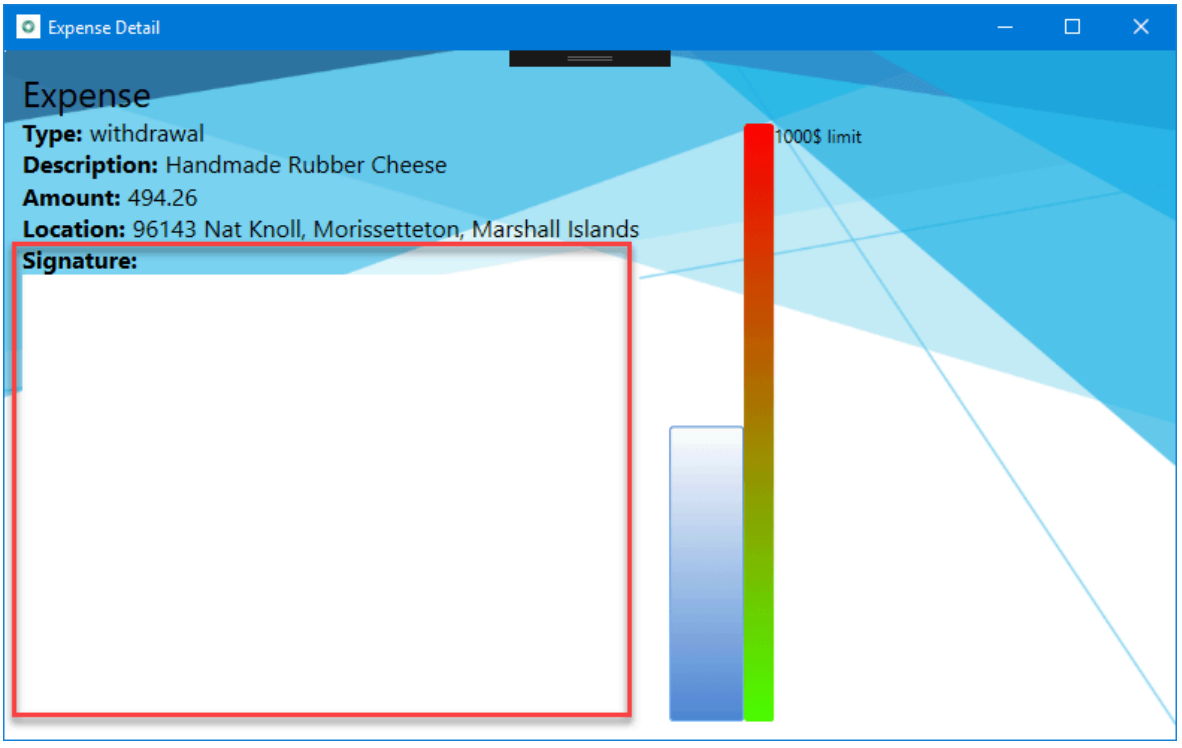
```
<TextBlock Text="Signature:" FontSize="16" FontWeight="Bold"
Grid.Row="5" />

<toolkit:InkCanvas x:Name="Signature" Grid.Row="6" />
```

4. Save the **ExpenseDetail.xaml** file.

5. Press F5 to run the app in the debugger.

6. Choose an employee from the list and then choose one of the available expenses. Notice that the expense detail page contains space for the **InkCanvas** control.



If you have a device which supports a digital pen, like a Surface, and you're running this lab on a physical machine, go on and try to use it. You will see the

digital ink appearing on the screen. However, if you don't have a pen capable device and you try to sign with your mouse, nothing will happen. This is happening because the **InkCanvas** control is enabled only for digital pens by default. However, we can change this behavior.

7. Close the app and double-click the **ExpenseDetail.xaml.cs** file under the **Views** folder of the **ContosoExpenses.Core** project.

8. Add the following namespace declaration at the top of the class:

```
C#

using Microsoft.Toolkit.Win32.UI.Controls.Interop.WinRT;
```

9. Locate the `ExpenseDetail()` constructor.

10. Add the following line of code after the `InitializeComponent()` method and save the code file.

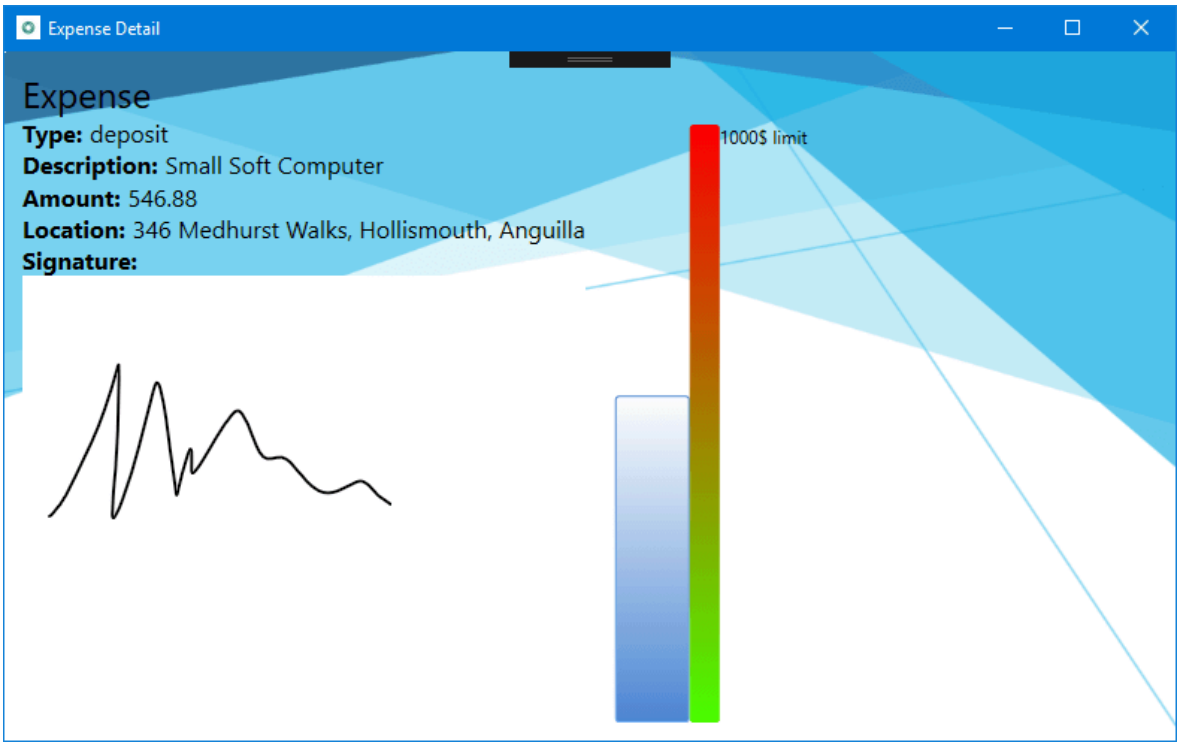
```
C#

Signature.InkPresenter.InputDeviceTypes = CoreInputDeviceTypes.Mouse |
CoreInputDeviceTypes.Pen;
```

    You can use the **InkPresenter** object to customize the default inking experience. This code uses the **InputDeviceTypes** property to enable mouse as well as pen input.

11. Press F5 again to rebuild and run the app in the debugger. Choose an employee from the list and then choose one of the available expenses.

12. Try now to draw something in the signature space with the mouse. This time, you'll see the ink appearing on the screen.



Next steps

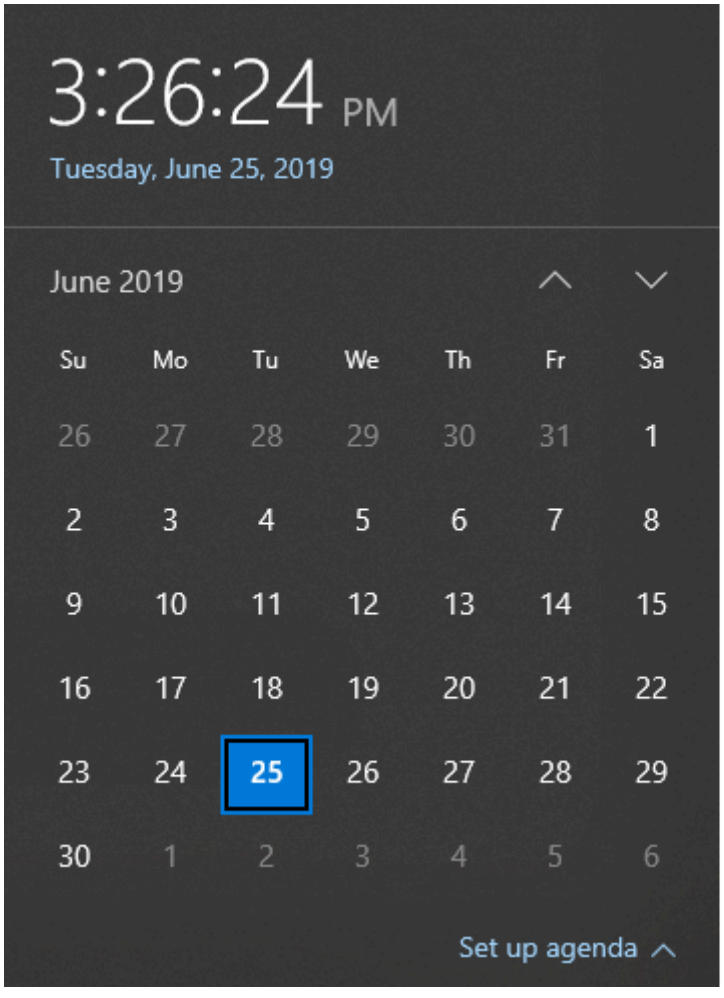
At this point in the tutorial, you have successfully added a UWP **InkCanvas** control to the Contoso Expenses app. You are now ready for Part 3: Add a UWP CalendarView control using XAML Islands.

Part 3: Add a UWP CalendarView control using XAML Islands

Article • 05/13/2022

This is the third part of a tutorial that demonstrates how to modernize a sample WPF desktop app named Contoso Expenses. For an overview of the tutorial, prerequisites, and instructions for downloading the sample app, see Tutorial: Modernize a WPF app. This article assumes you have already completed part 2.

In the fictional scenario of this tutorial, the Contoso development team wants to make it easier to choose the date for an expense report on a touch-enabled device. In this part of the tutorial, you will add a UWP CalendarView control to the app. This is the same control that is used in the Windows date and time functionality on the taskbar.



Unlike the **InkCanvas** control you added in part 2, the Windows Community Toolkit does not provide a wrapped version of the UWP **CalendarView** that can be used in WPF apps. As an alternative, you'll host an **InkCanvas** in the generic WindowsXamlHost control. You can use this control to host any first-party UWP control provided by the Windows SDK or WinUI library or any custom UWP control created by a third party. The

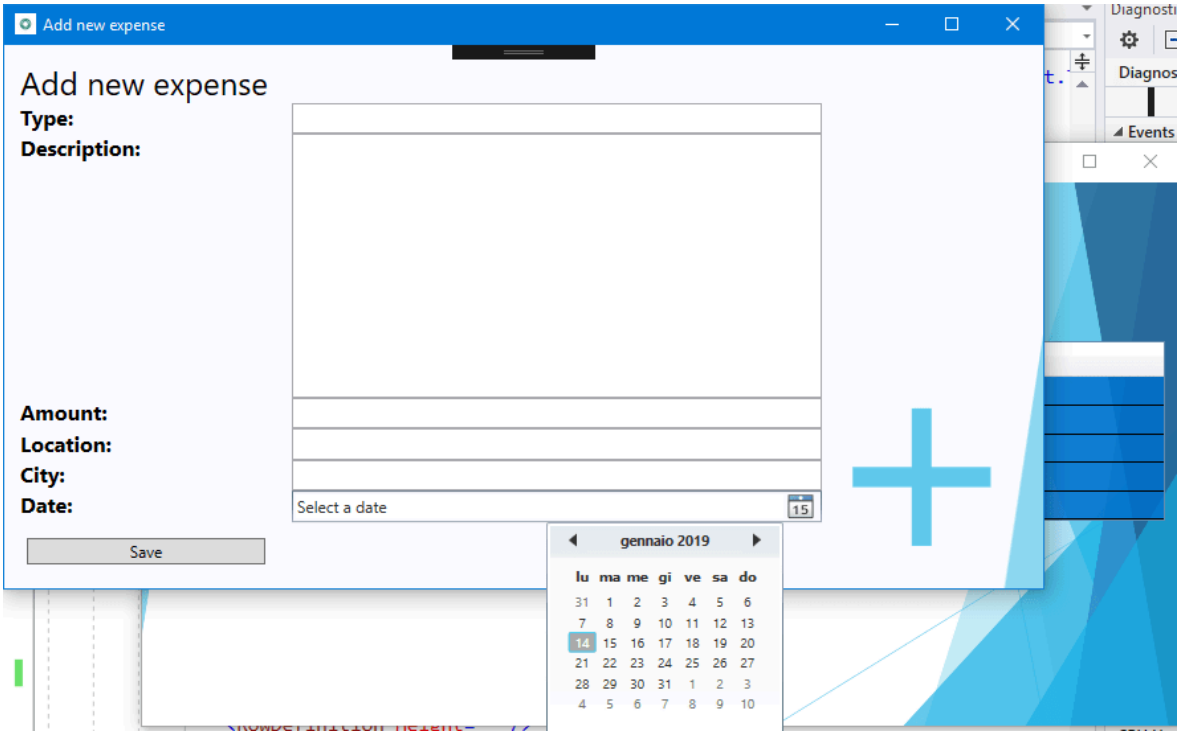
WindowsXamlHost control is provided by the `Microsoft.Toolkit.Wpf.UI.XamlHost` package NuGet package. This package is included with the `Microsoft.Toolkit.Wpf.UI.Controls` NuGet package that you installed in part 2.

> **Note**
>
> This tutorial only demonstrates how to use WindowsXamlHost to host the first-party **CalendarView** control provided by the Windows SDK. For a walkthrough that demonstrates how to host a custom control, see Host a custom UWP control in a WPF app using XAML Islands.

In order to use the **WindowsXamlHost** control, you'll need to directly call WinRT APIs from code in the WPF app. The `Microsoft.Windows.SDK.Contracts` NuGet package contains the references necessary to enable you to call WinRT APIs from the app. This package is also included in the `Microsoft.Toolkit.Wpf.UI.Controls` NuGet package that you installed in part 2.

Add the WindowsXamlHost control

1. In **Solution Explorer**, expand the **Views** folder in the **ContosoExpenses.Core** project and double-click the **AddNewExpense.xaml** file. This is the form used to add a new expense to the list. Here is how it appears in the current version of the app.



The date picker control included in WPF is meant for traditional computers with mouse and keyboard. Choosing a date with a touch screen isn't really feasible, due to the small size of the control and the limited space between each day in the calendar.

2. At the top of the **AddNewExpense.xaml** file, add the following attribute to the **Window** element.

```
XML

xmlns:xamlhost="clr-
namespace:Microsoft.Toolkit.Wpf.UI.XamlHost;assembly=Microsoft.Toolkit.
Wpf.UI.XamlHost"
```

After adding this attribute, the **Window** element should now look like this.

```
XML

<Window x:Class="ContosoExpenses.Views.AddNewExpense"

xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-
compatibility/2006"
        xmlns:xamlhost="clr-
namespace:Microsoft.Toolkit.Wpf.UI.XamlHost;assembly=Microsoft.Toolkit.
Wpf.UI.XamlHost"
        DataContext="{Binding Source={StaticResource
ViewModelLocator},Path=AddNewExpenseViewModel}"
        xmlns:local="clr-namespace:ContosoExpenses"
        mc:Ignorable="d"
        Title="Add new expense" Height="450" Width="800"
        Background="{StaticResource AddNewExpenseBackground}">
```

3. Change the **Height** attribute of the **Window** element from 450 to 800. This is needed because the UWP **CalendarView** control takes more space than the WPF date picker.

```
XML

<Window x:Class="ContosoExpenses.Views.AddNewExpense"

xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-
compatibility/2006"
        xmlns:xamlhost="clr-
```

```
namespace:Microsoft.Toolkit.Wpf.UI.XamlHost;assembly=Microsoft.Toolkit.
Wpf.UI.XamlHost"
        DataContext="{Binding Source={StaticResource
ViewModelLocator},Path=AddNewExpenseViewModel}"
        xmlns:local="clr-namespace:ContosoExpenses"
        mc:Ignorable="d"
        Title="Add new expense" Height="800" Width="800"
        Background="{StaticResource AddNewExpenseBackground}">
```

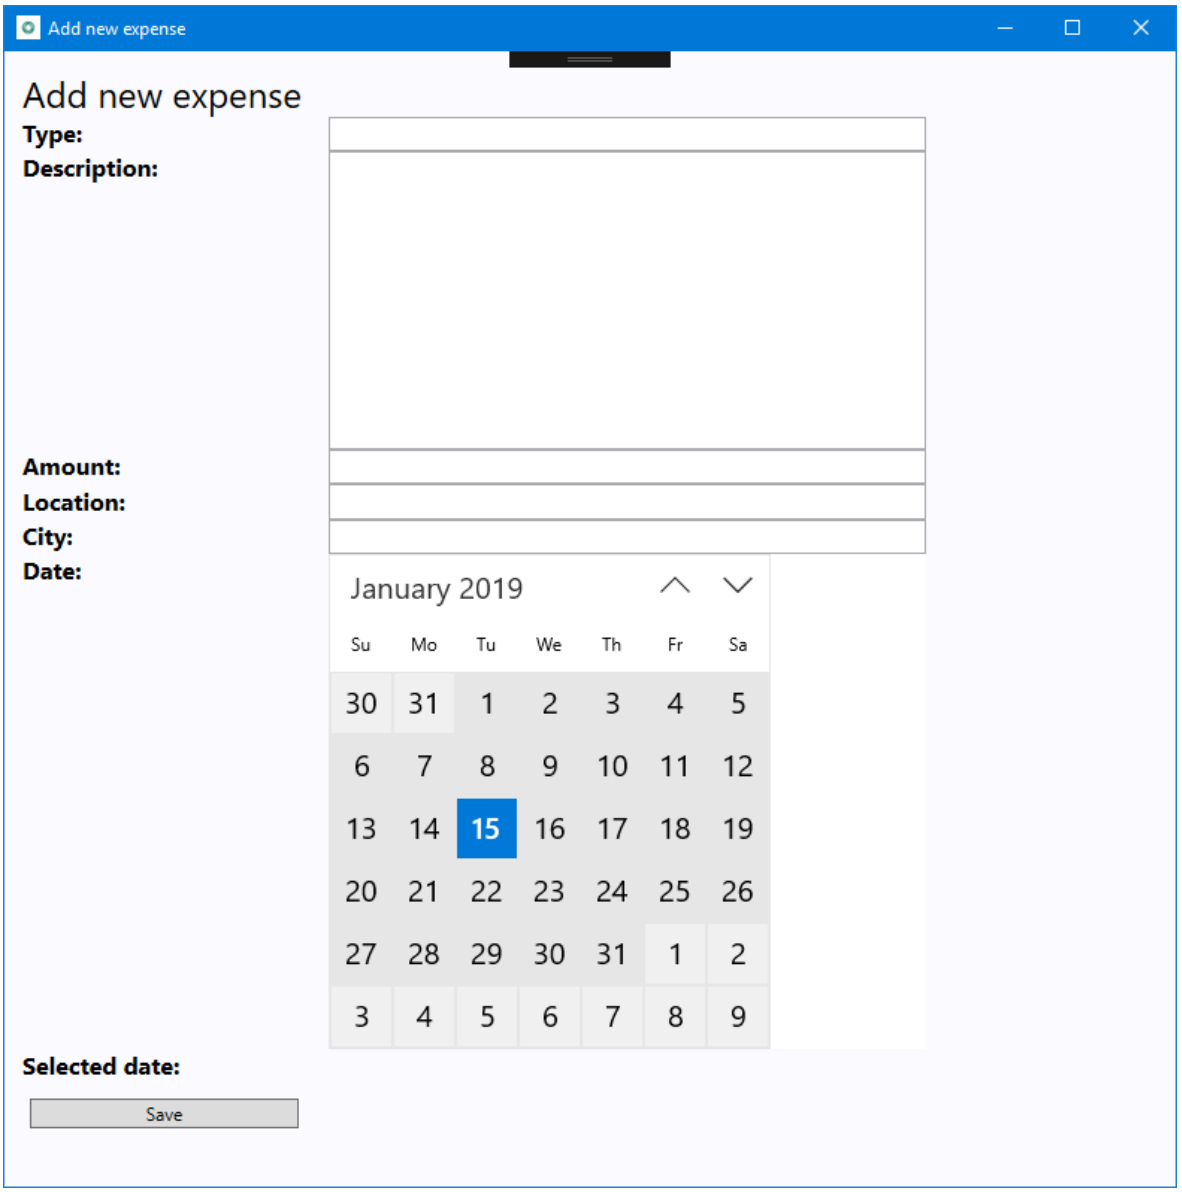
4. Locate the `DatePicker` element near the bottom of the file, and replace this element with the following XAML.

```
XML

<xamlhost:WindowsXamlHost
InitialTypeName="Windows.UI.Xaml.Controls.CalendarView" Grid.Column="1"
Grid.Row="6" Margin="5, 0, 0, 0" x:Name="CalendarUwp"  />
```

   This XAML adds the **WindowsXamlHost** control. The **InitialTypeName** property indicates the full name of the UWP control you want to host (in this case, **Windows.UI.Xaml.Controls.CalendarView**).

5. Press F5 to build and run the app in the debugger. Choose an employee from the list and then press the **Add new expense** button. Confirm that the following page hosts the new UWP **CalendarView** control.



6. Close the app.

Interact with the WindowsXamlHost control

Next, you'll update the app to process the selected date, display it on the screen, and populate the **Expense** object to save in the database.

The UWP CalendarView contains two members that are relevant for this scenario:

- The **SelectedDates** property contains the date selected by the user.
- The **SelectedDatesChanged** event is raised when the user selects a date.

However, the **WindowsXamlHost** control is a generic host control for *any* kind of UWP control. As such, it doesn't expose a property called **SelectedDates** or an event called **SelectedDatesChanged**, because they are specific of the **CalendarView** control. To access these members, you must write code that casts the **WindowsXamlHost** to the **CalendarView** type. The best place to do this is in response to the **ChildChanged** event

of the **WindowsXamlHost** control, which is raised when the hosted control has been rendered.

1. In the **AddNewExpense.xaml** file, add an event handler for the **ChildChanged** event of the **WindowsXamlHost** control you added earlier. When you are done, the **WindowsXamlHost** element should look like this.

```
XML
```

```
<xamlhost:WindowsXamlHost
InitialTypeName="Windows.UI.Xaml.Controls.CalendarView" Grid.Column="1"
Grid.Row="6" Margin="5, 0, 0, 0" x:Name="CalendarUwp"
ChildChanged="CalendarUwp_ChildChanged" />
```

2. In the same file, locate the **Grid.RowDefinitions** element of the main **Grid**. Add one more **RowDefinition** element with the **Height** equal to **Auto** at the end of the list of child elements. When you are done, the **Grid.RowDefinitions** element should look like this (there should now be 9 **RowDefinition** elements).

```
XML
```

```
<Grid.RowDefinitions>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
    <RowDefinition Height="Auto"/>
</Grid.RowDefinitions>
```

3. Add the following XAML after the **WindowsXamlHost** element and before the **Button** element near the end of the file.

```
XML
```

```
<TextBlock Text="Selected date:" FontSize="16" FontWeight="Bold"
Grid.Row="7" Grid.Column="0" />
<TextBlock Text="{Binding Path=Date}" FontSize="16" Grid.Row="7"
Grid.Column="1" />
```

4. Locate the **Button** element near the end of the file and change the **Grid.Row** property from **7** to **8**. This shifts the button down one row in the grid because you added a new row.

XML

```
<Button Content="Save" Grid.Row="8" Grid.Column="0" Command="{Binding
Path=SaveExpenseCommand}" Margin="5, 12, 0, 0"
HorizontalAlignment="Left" Width="180" />
```

5. Open the **AddNewExpense.xaml.cs** code file.

6. Add the following statement to the top of the file.

C#

```
using Microsoft.Toolkit.Wpf.UI.XamlHost;
```

7. Add the following event handler to the `AddNewExpense` class. This code implements the **ChildChanged** event of the **WindowsXamlHost** control you declared earlier in the XAML file.

C#

```
private void CalendarUwp_ChildChanged(object sender, System.EventArgs
e)
{
    WindowsXamlHost windowsXamlHost = (WindowsXamlHost)sender;

    Windows.UI.Xaml.Controls.CalendarView calendarView =
        (Windows.UI.Xaml.Controls.CalendarView)windowsXamlHost.Child;

    if (calendarView != null)
    {
        calendarView.SelectedDatesChanged += (obj, args) =>
        {
            if (args.AddedDates.Count > 0)
            {
                Messenger.Default.Send<SelectedDateMessage>(new
SelectedDateMessage(args.AddedDates[0].DateTime));
            }
        };
    }
}
```

This code uses the **Child** property of the **WindowsXamlHost** control to access the UWP **CalendarView** control. The code then subscribes to the **SelectedDatesChanged** event, which is triggered when the user selects a date from the calendar. This event handler passes the selected date to the ViewModel where the new **Expense** object is created and saved to the database. To do this, the code uses the messaging infrastructure provided by the MVVM Light NuGet package.

The code sends a message called **SelectedDateMessage** to the ViewModel, which will receive it and set the **Date** property with the selected value. In this scenario the **CalendarView** control is configured for single selection mode, so the collection will contain only one element.

At this point, the project still won't compile because it is missing the implementation for the **SelectedDateMessage** class. The following steps implement this class.

8. In **Solution Explorer**, right-click the **Messages** folder and choose **Add -> Class**. Name the new class **SelectedDateMessage** and click **Add**.

9. Replace the contents of the **SelectedDateMessage.cs** code file with the following code. This code adds a using statement for the `GalaSoft.MvvmLight.Messaging` namespace (from the MVVM Light NuGet package), inherits from the **MessageBase** class, and adds **DateTime** property that is initialized through the public constructor. When you are done, the file should look like this.

```
C#
```

```
using GalaSoft.MvvmLight.Messaging;
using System;

namespace ContosoExpenses.Messages
{
    public class SelectedDateMessage: MessageBase
    {
        public DateTime SelectedDate { get; set; }

        public SelectedDateMessage(DateTime selectedDate)
        {
            this.SelectedDate = selectedDate;
        }
    }
}
```

10. Next, you'll update the ViewModel to receive this message and populate the **Date** property of the ViewModel. In **Solution Explorer**, expand the **ViewModels** folder and open the **AddNewExpenseViewModel.cs** file.

11. Locate the public constructor for the `AddNewExpenseViewModel` class and add the following code to the end of the constructor. This code registers to receive the **SelectedDateMessage**, extract the selected date from it through the **SelectedDate** property, and we use it to set the **Date** property exposed by the ViewModel. Because this property is bound with the **TextBlock** control you added earlier, you can see the date selected by the user.

```
C#

Messenger.Default.Register<SelectedDateMessage>(this, message =>
{
    Date = message.SelectedDate;
});
```

When you are done, the `AddNewExpenseViewModel` constructor should look like this.

```
C#

public AddNewExpenseViewModel(IDatabaseService databaseService,
IStorageService storageService)
{
    this.databaseService = databaseService;
    this.storageService = storageService;

    Date = DateTime.Today;

    Messenger.Default.Register<SelectedDateMessage>(this, message =>
    {
        Date = message.SelectedDate;
    });
}
```

> **Note**
>
> The `SaveExpenseCommand` method in the same code file does the work of saving the expenses to the database. This method uses the **Date** property to create the new **Expense** object. This property is now being populated by the **CalendarView** control through the `SelectedDateMessage` message you just created.

12. Press F5 to build and run the app in the debugger. Choose one of the available employees and then click the **Add new expense** button. Complete all fields in the form and choose a date from the new **CalendarView** control. Confirm the selected date is displayed as a string below the control.

13. Press the **Save** button. The form will be closed and the new expense is added to the end of the list of expenses. The first column with the expense date should be the date you selected in the **CalendarView** control.

Next steps

At this point in the tutorial, you have successfully replaced a WPF date time control with the UWP **CalendarView** control, which supports touch and digital pens in addition to mouse and keyboard input. Although the Windows Community Toolkit doesn't provide a wrapped version of the UWP **CalendarView** control that can be used directly in a WPF app, you were able to host the control by using the generic WindowsXamlHost control.

You are now ready for Part 4: Add Windows user activities and notifications.

Part 4: Add Windows user activities and notifications

Article • 05/13/2022

This is the fourth part of a tutorial that demonstrates how to modernize a sample WPF desktop app named Contoso Expenses. For an overview of the tutorial, prerequisites, and instructions for downloading the sample app, see Tutorial: Modernize a WPF app. This article assumes you have already completed part 3.

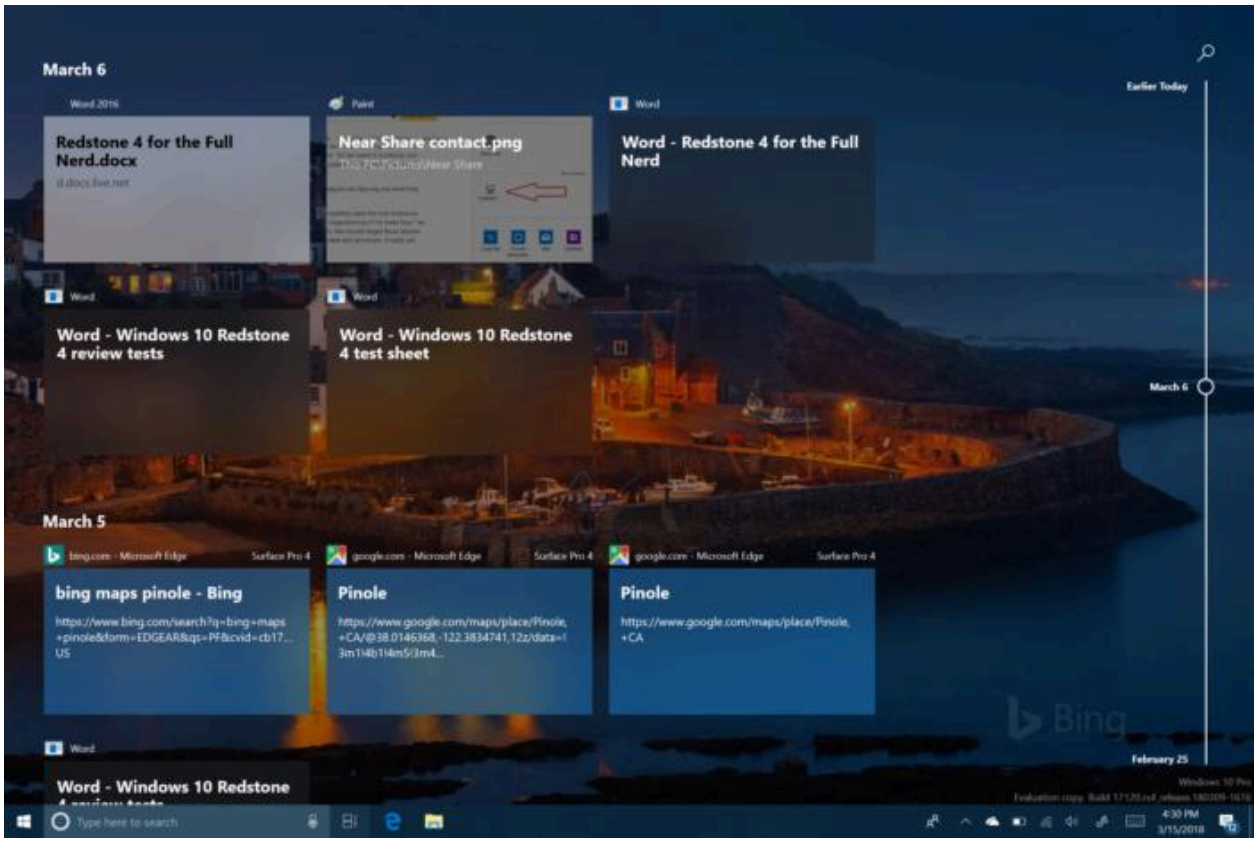
In the previous parts of this tutorial you added UWP XAML controls to the app using XAML Islands. As a byproduct of this, you also enabled the app to call any WinRT API. This opens up the opportunity for the app to use many other features offered by Windows, not just UWP XAML controls.

In the fictional scenario of this tutorial, the Contoso development team has decided to add two new features to the app: activities and notifications. This part of the tutorial shows how to implement these features.

Add a user activity

> **Note**
>
> The timeline feature is discontinued since Windows 11

In Windows 10, apps can track activities performed by the user such as opening a file or displaying a specific page. These activities are then made available through Timeline, a feature introduced in Windows 10 version 1803, which allows the user to quickly go back to the past and resume an activity they started previously.



User activities are tracked using Microsoft Graph. However, when you're building a Windows 10 app, you don't need to interact directly with the REST endpoints provided by Microsoft Graph. Instead, you can use a convenient set of WinRT APIs. We're going to use these WinRT APIs in the Contoso Expenses app to track every time the user opens an expense within the app, and use Adaptive Cards to enable users to create the activity.

Introduction to Adaptive Cards

This section provides a brief overview of Adaptive Cards. If you don't need this information, you can skip this and go right to the add an Adaptive Card instructions.

Adaptive Cards enable developers to exchange card content in a common and consistent way. An Adaptive Card is described by a JSON payload that defines its content, which can include text, images, actions, and more.

An Adaptive Card defines just the content and not the visual appearance of the content. The platform where the Adaptive Card is received can render the content using the most appropriate styling. The way Adaptive Cards are designed is through a renderer, which is able to take the JSON payload and to convert it into native UI. For example, the UI could be XAML for a WPF or UWP app, AXML for an Android app, or HTML for a website or a bot chat.

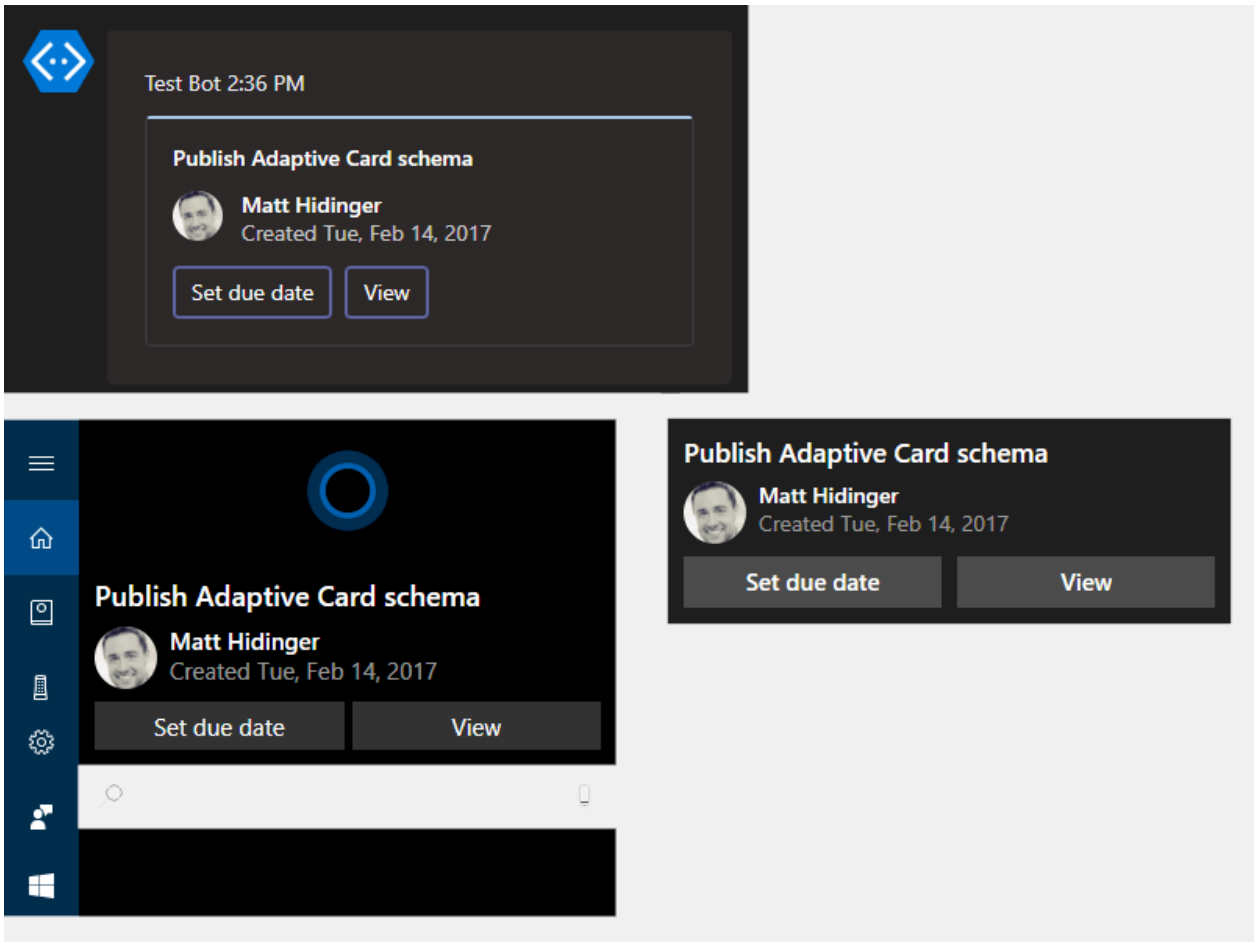
Here is an example of a simple Adaptive Card payload.

```
JSON
```

```
{
    "type": "AdaptiveCard",
    "body": [
        {
            "type": "Container",
            "items": [
                {
                    "type": "TextBlock",
                    "size": "Medium",
                    "weight": "Bolder",
                    "text": "Publish Adaptive Card schema"
                },
                {
                    "type": "ColumnSet",
                    "columns": [
                        {
                            "type": "Column",
                            "items": [
                                {
                                    "type": "Image",
                                    "style": "Person",
                                    "url":
"https://pbs.twimg.com/profile_images/3647943215/d7f12830b3c17a5a9e4afcc370e
3a37e_400x400.jpeg",
                                    "size": "Small"
                                }
                            ],
                            "width": "auto"
                        },
                        {
                            "type": "Column",
                            "items": [
                                {
                                    "type": "TextBlock",
                                    "weight": "Bolder",
                                    "text": "Matt Hidinger",
                                    "wrap": true
                                },
                                {
                                    "type": "TextBlock",
                                    "spacing": "None",
                                    "text": "Created {{DATE(2017-02-
14T06:08:39Z,SHORT)}}",
                                    "isSubtle": true,
                                    "wrap": true
                                }
                            ],
                            "width": "stretch"
                        }
                    ]
                }
            ]
        }
    ],
```

```
    "actions": [
        {
            "type": "Action.ShowCard",
            "title": "Set due date",
            "card": {
                "type": "AdaptiveCard",
                "style": "emphasis",
                "body": [
                    {
                        "type": "Input.Date",
                        "id": "dueDate"
                    },
                    {
                        "type": "Input.Text",
                        "id": "comment",
                        "placeholder": "Add a comment",
                        "isMultiline": true
                    }
                ],
                "actions": [
                    {
                        "type": "Action.OpenUrl",
                        "title": "OK",
                        "url": "http://adaptivecards.io"
                    }
                ],
                "$schema": "http://adaptivecards.io/schemas/adaptive-
card.json"
            }
        },
        {
            "type": "Action.OpenUrl",
            "title": "View",
            "url": "http://adaptivecards.io"
        }
    ],
    "$schema": "http://adaptivecards.io/schemas/adaptive-card.json",
    "version": "1.0"
}
```

The image below shows how this JSON is rendered in different ways by ta Teams channel, Cortana and a Windows notification.



Adaptive cards play an important role in Timeline because it's the way Windows renders activities. Each thumbnail displayed inside Timeline is actually an Adaptive Card. As such, when you're going to create a user activity inside your app, you will be asked to provide an Adaptive Card to render it.

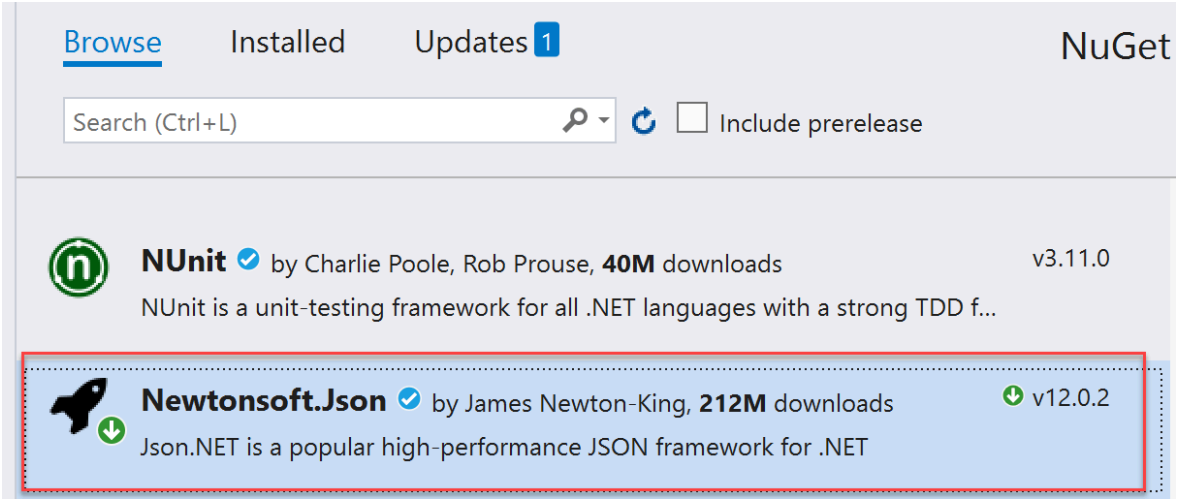
> ⓘ Note
>
> A great way to brainstorm the design of an Adaptive Card is using the online designer. You will have the chance to design the card with building blocks (images, texts, columns, etc) and get the corresponding JSON. After you have an idea of the final design, you can use a library called Adaptive Cards to make it easier to build your Adaptive Card using C# classes instead of plain JSON, which might be hard to debug and build.

Add an Adaptive Card

1. Right click on the **ContosoExpenses.Core** project in Solution Explorer and choose **Manage NuGet packages**.

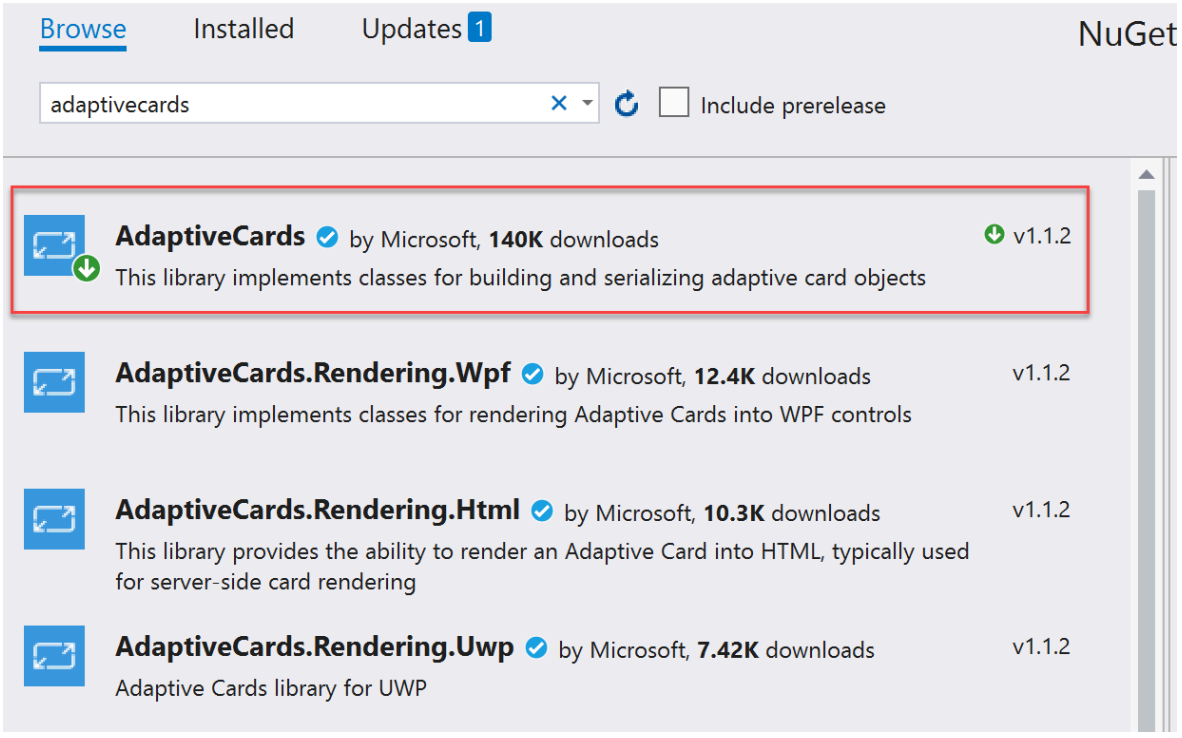
2. In the **NuGet Package Manager** window, click **Browse**. Search for the `Newtonsoft.Json` package and install the latest available version. This is a popular

JSON manipulation library that you will use to help manipulate the JSON strings required by Adaptive Cards.



> **Note**
>
> If you don't install the `Newtonsoft.Json` package separately, The Adaptive Cards library will reference an older version of the `Newtonsoft.Json` package that doesn't support .NET Core 3.0.

3. In the **NuGet Package Manager** window, click **Browse**. Search for the `AdaptiveCards` package and install the latest available version.



4. In **Solution Explorer**, right-click the **ContosoExpenses.Core** project, choose **Add -> Class**. Name the class **TimelineService.cs** and click **OK**.

5. In the **TimelineService.cs** file, add the following statements to the top of the file.

```
C#

using AdaptiveCards;
using ContosoExpenses.Data.Models;
```

6. Change the namespace declared in the file from `ContosoExpenses.Core` to `ContosoExpenses`.

7. Add the following method to the `TimelineService` class.

```
C#

 private string BuildAdaptiveCard(Expense expense)
 {
     AdaptiveCard card = new AdaptiveCard("1.0");

     AdaptiveTextBlock title = new AdaptiveTextBlock
     {
         Text = expense.Description,
         Size = AdaptiveTextSize.Medium,
         Wrap = true
     };

     AdaptiveColumnSet columnSet = new AdaptiveColumnSet();
     AdaptiveColumn photoColumn = new AdaptiveColumn
     {
         Width = "auto"
     };

     AdaptiveImage image = new AdaptiveImage
     {
         Url = new
Uri("https://appmodernizationworkshop.blob.core.windows.net/contosoexpe
nses/Contoso192x192.png"),
         Size = AdaptiveImageSize.Small,
         Style = AdaptiveImageStyle.Default
     };
     photoColumn.Items.Add(image);

     AdaptiveTextBlock amount = new AdaptiveTextBlock
     {
         Text = expense.Cost.ToString(),
         Weight = AdaptiveTextWeight.Bolder,
         Wrap = true
     };

     AdaptiveTextBlock date = new AdaptiveTextBlock
     {
         Text = expense.Date.Date.ToShortDateString(),
         IsSubtle = true,
```

```
            Spacing = AdaptiveSpacing.None,
            Wrap = true
        };

        AdaptiveColumn expenseColumn = new AdaptiveColumn
        {
            Width = "stretch"
        };
        expenseColumn.Items.Add(amount);
        expenseColumn.Items.Add(date);

        columnSet.Columns.Add(photoColumn);
        columnSet.Columns.Add(expenseColumn);

        card.Body.Add(title);
        card.Body.Add(columnSet);

        string json = card.ToJson();
        return json;
    }
```

About the code

This method receives an **Expense** object with all the information about the expense to render and it builds a new **AdaptiveCard** object. The method adds the following to the card:

- A title, which uses the description of the expense.
- An image, which is the Contoso logo.
- The amount of the expense.
- The date of the expense.

The last 3 elements are split into two different columns, so that the Contoso logo and the details about the expense can be placed side by side. After the object is built, the method returns the corresponding JSON string with the help of the **ToJson** method.

Define the user activity

Now that you have defined the Adaptive Card, you can create a user activity based on it.

1. Add the following statements to the top of **TimelineService.cs** file:

```
C#
```

```
using Windows.ApplicationModel.UserActivities;
using System.Threading.Tasks;
```

```
using Windows.UI.Shell;
```

> **Note**
>
> These are UWP namespaces. These resolve because the `Microsoft.Toolkit.Wpf.UI.Controls` NuGet package that you installed in step 2 includes a reference to the `Microsoft.Windows.SDK.Contracts` package, which enables the **ContosoExpenses.Core** project to reference WinRT APIs even though it is a .NET Core 3 project.

2. Add the following field declarations to the `TimelineService` class.

C#

```
private UserActivityChannel _userActivityChannel;
private UserActivity _userActivity;
private UserActivitySession _userActivitySession;
```

3. Add the following method to the `TimelineService` class.

C#

```
public async Task AddToTimeline(Expense expense)
{
    _userActivityChannel = UserActivityChannel.GetDefault();
    _userActivity = await
_userActivityChannel.GetOrCreateUserActivityAsync($"Expense-
{expense.ExpenseId}");

    _userActivity.ActivationUri = new
Uri($"contosoexpenses://expense/{expense.ExpenseId}");
    _userActivity.VisualElements.DisplayText = "Contoso Expenses";

    string json = BuildAdaptiveCard(expense);

    _userActivity.VisualElements.Content =
AdaptiveCardBuilder.CreateAdaptiveCardFromJson(json);

    await _userActivity.SaveAsync();
    _userActivitySession?.Dispose();
    _userActivitySession = _userActivity.CreateSession();
}
```

4. Save the changes to **TimelineService.cs**.

About the code

The `AddToTimeline` method first gets a **UserActivityChannel** object that is required to store user activities. Then it creates a new user activity using the **GetOrCreateUserActivityAsync** method, which requires a unique identifier. This way, if an activity already exists, the app can update it; otherwise it will create a new one. The identifier to pass depends by the kind of application you're building:

- If you want to always update the same activity so that Timeline will only show the most recent one, you can use a fixed identifier (such as **Expenses**).
- If you want to track every activity as a different one, so that Timeline will display all of them, you can use a dynamic identifier.

In this scenario, the app will track each opened expense as a different user activity, so the code creates each identifier by using the keyword **Expense-** followed by the unique expense ID.

After the method creates a **UserActivity** object, it populates the object with the following info:

- An **ActivationUri** that is invoked when the user clicks on the activity in Timeline. The code uses a custom protocol called **contosoexpenses** that the app will handle later.
- The **VisualElements** object, which contains a set of properties that define the visual appearance of the activity. This code sets the **DisplayText** (which is the title displayed on top of the entry in Timeline) and the **Content**.

This is where the Adaptive Card you defined earlier plays a role. The app passes the Adaptive Card you designed earlier as content to the method. However, Windows 10 uses a different object to represent a card compared to the one used by the `AdaptiveCards` NuGet package. Therefore, the method recreates the card by using the **CreateAdaptiveCardFromJson** method exposed by the **AdaptiveCardBuilder** class. After the method creates the user activity, it saves the activity and creates a new session.

When a user clicks on an activity in Timeline, the **contosoexpenses://** protocol will be activated and the URL will include the information the app needs to retrieve the selected expense. As an optional task, you could implement the protocol activation so that the application reacts properly when the user uses Timeline.

Integrate the application with Timeline

Now that you have created a class that interacts with Timeline, we can start using it to enhance the application's experience. The best place to use the **AddToTimeline** method

exposed by the **TimelineService** class is when the user opens the detail page of an expense.

1. In the **ContosoExpenses.Core** project, expand the **ViewModels** folder and open the **ExpenseDetailViewModel.cs** file. This is the ViewModel that supports the expense detail's window.

2. Locate the public constructor of the **ExpenseDetailViewModel** class and add the following code at the end of the constructor. Whenever the expense window is opened, the method calls the **AddToTimeline** method and passes the current expense. The **TimelineService** class uses this info to create a user activity using the expense information.

   C#

   ```
   TimelineService timeline = new TimelineService();
   timeline.AddToTimeline(expense);
   ```

   When you are done, the constructor should look like this.

   C#

   ```
   public ExpensesDetailViewModel(IDatabaseService databaseService,
   IStorageService storageService)
   {
       var expense =
   databaseService.GetExpense(storageService.SelectedExpense);

       ExpenseType = expense.Type;
       Description = expense.Description;
       Location = expense.Address;
       Amount = expense.Cost;

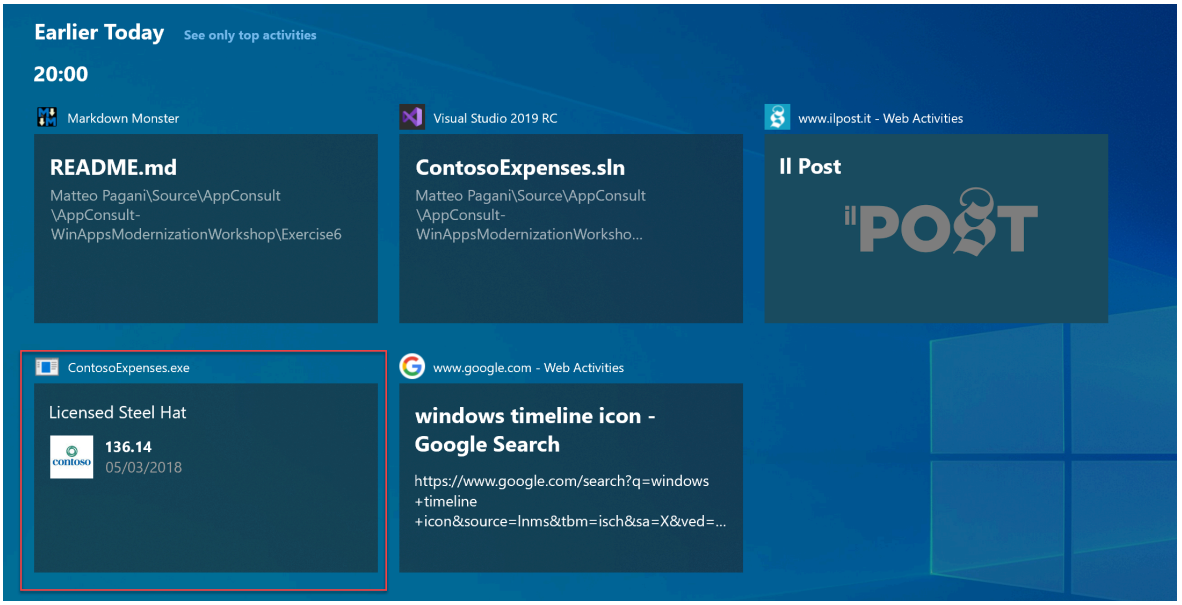
       TimelineService timeline = new TimelineService();
       timeline.AddToTimeline(expense);
   }
   ```

3. Press F5 to build and run the app in the debugger. Choose an employee from the list and then choose an expense. In the detail page, note the description of the expense, the date and the amount.

4. Press **Start + TAB** to open Timeline.

5. Scroll down the list of currently opened applications until you see the section titled **Earlier today**. This section shows some of your most recent user activities. Click the **See all activities** link next to the **Earlier today** heading.

6. Confirm that you see a new card with the information about the expense you have just selected in the application.



7. If you now open other expenses, you will see new cards being added as user activities. Remember that the code uses a different identifier for each activity, so it creates a card for each expense you open in the app.

8. Close the app.

Add a notification

The second feature the Contoso development team wants to add is a notification that is shown to the user whenever a new expense is saved to the database. To do this, you can leverage the built-in notifications system in Windows 10, which is exposed to developers via WinRT APIs. This notification system has many advantages:

- Notifications are consistent with the rest of the OS.
- They are actionable.
- They get stored in Action Center so they can be reviewed later.

To add a notification to the app:

1. In **Solution Explorer**, right-click the **ContosoExpenses.Core** project, choose **Add -> Class**. Name the class **NotificationService.cs** and click **OK**.

2. In the **NotificationService.cs** file, add the following statements to the top of the file.

```
C#
```

```
using Windows.Data.Xml.Dom;
using Windows.UI.Notifications;
```

3. Change the namespace declared in the file from `ContosoExpenses.Core` to `ContosoExpenses`.

4. Add the following method to the `NotificationService` class.

```
C#
```

```
public void ShowNotification(string description, double amount)
{
    string xml = $@"<toast>
                      <visual>
                        <binding template='ToastGeneric'>
                          <text>Expense added</text>
                          <text>Description: {description} - Amount:
{amount} </text>
                        </binding>
                      </visual>
                    </toast>";

    XmlDocument doc = new XmlDocument();
    doc.LoadXml(xml);

    ToastNotification toast = new ToastNotification(doc);
    ToastNotificationManager.CreateToastNotifier().Show(toast);
}
```

Toast notifications are represented by an XML payload, which can include text, images, actions, and more. You can find all the supported elements here. This code uses a very simple schema with two lines of text: the title and the body. After the code defines the XML payload and loads it in an **XmlDocument** object, it wraps the XML in a **ToastNotification** object and shows it by using the **ToastNotificationManager** class.

5. In the **ContosoExpenses.Core** project, expand the **ViewModels** folder and open the **AddNewExpenseViewModel.cs** file.

6. Locate the `SaveExpenseCommand` method, which is triggered when the user presses on the button to save a new expense. Add the following code to this method, just after the call to the `SaveExpense` method.

```
C#
```

```
NotificationService notificationService = new NotificationService();
notificationService.ShowNotification(expense.Description,
```

```
expense.Cost);
```

When you are done, the `SaveExpenseCommand` method should look like this.

C#

```
private RelayCommand _saveExpenseCommand;
public RelayCommand SaveExpenseCommand
{
    get
    {
        if (_saveExpenseCommand == null)
        {
            _saveExpenseCommand = new RelayCommand(() =>
            {
                Expense expense = new Expense
                {
                    Address = Address,
                    City = City,
                    Cost = Cost,
                    Date = Date,
                    Description = Description,
                    EmployeeId = storageService.SelectedEmployeeId,
                    Type = ExpenseType
                };

                databaseService.SaveExpense(expense);

                NotificationService notificationService = new
NotificationService();

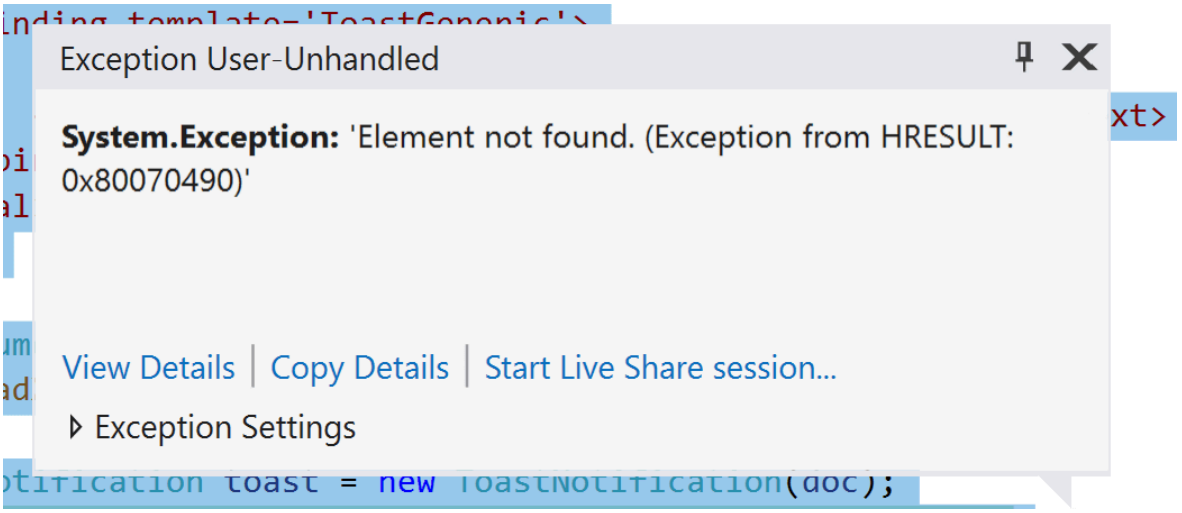
notificationService.ShowNotification(expense.Description,
expense.Cost);

                Messenger.Default.Send<UpdateExpensesListMessage>(new
UpdateExpensesListMessage());
                Messenger.Default.Send<CloseWindowMessage>(new
CloseWindowMessage());
            }, () => IsFormFilled
            );
        }

        return _saveExpenseCommand;
    }
}
```

7. Press F5 to build and run the app in the debugger. Choose an employee from the list and then click the **Add new expense** button. Complete all fields in the form and press **Save**.

8. You will receive the following exception.



This exception is caused by the fact that the Contoso Expenses app doesn't yet have package identity. Some WinRT APIs, including the notifications API, require package identity before they can be used in an app. UWP apps receive package identity by default because they can only be distributed via MSIX packages. Other types of Windows apps, including WPF apps, can also be deployed via MSIX packages to obtain package identity. The next part of this tutorial will explore how to do this.

Next steps

At this point in the tutorial, you have successfully added a user activity to the app that integrates with Windows Timeline, and you have also added a notification to the app that is triggered when users create a new expense. However, the notification doesn't yet work because the app requires package identity to use the notifications API. To learn how to build an MSIX package for the app to obtain package identity and gain other deployment benefits, see Part 5: Package and deploy with MSIX.

Part 5: Package and deploy with MSIX

Article • 02/09/2022

This is the final part of a tutorial that demonstrates how to modernize a sample WPF desktop app named Contoso Expenses. For an overview of the tutorial, prerequisites, and instructions for downloading the sample app, see Tutorial: Modernize a WPF app. This article assumes you have already completed part 4.

In part 4 you learned that some WinRT APIs, including the notifications API, require package identity before they can be used in an app. You can obtain package identity by packaging Contoso Expenses using MSIX, the packaging format introduced in Windows 10 to package and deploy Windows applications. MSIX provides advantages for developers and IT Pros, including:

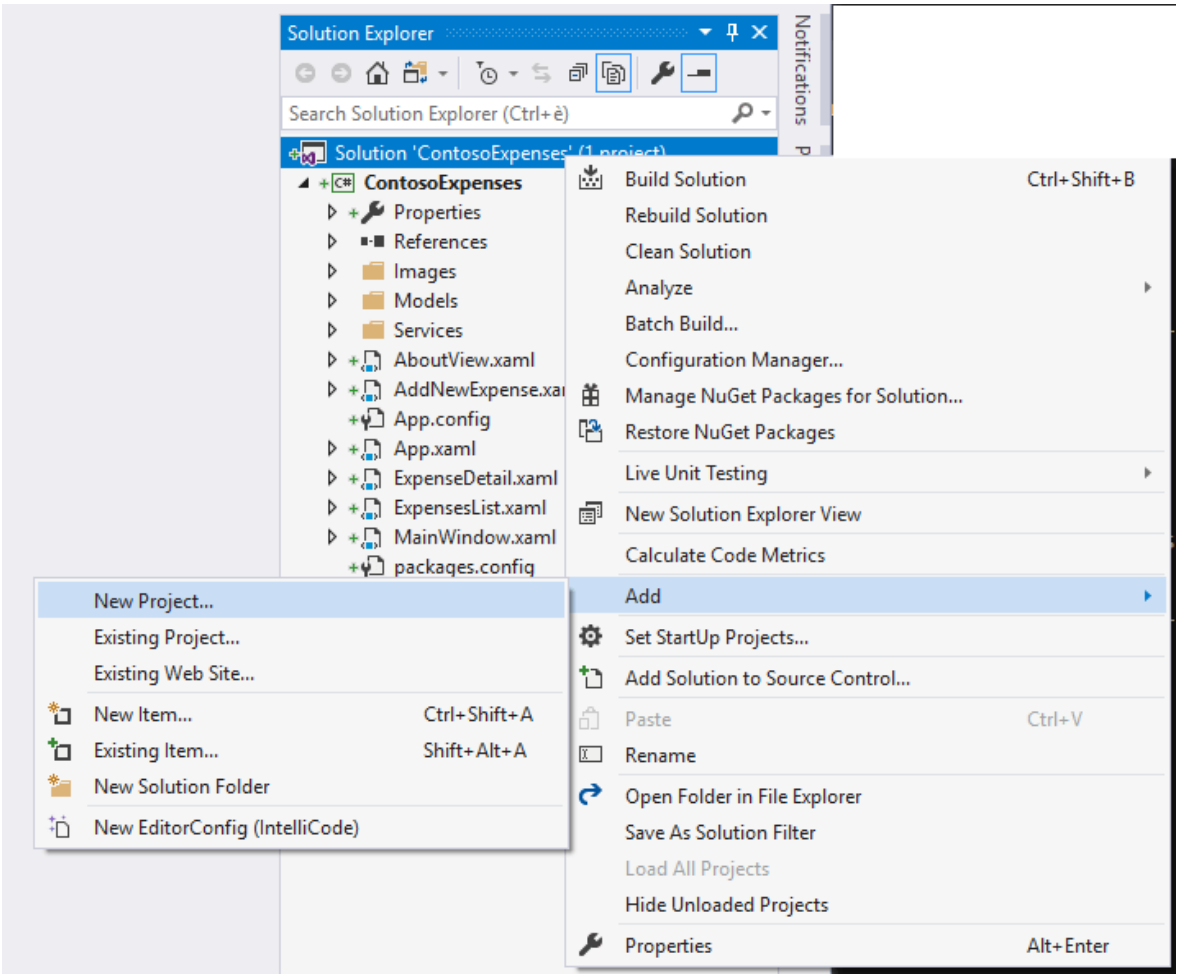
- Optimized network usage and storage space.
- Complete clean uninstall, thanks to a lightweight container where the app is executed. No registry keys and temporary files are left on the system.
- Decouples OS updates from application updates and customizations.
- Simplifies the install, update, and uninstall process.

In this part of the tutorial you'll learn how to package the Contoso Expenses app in an MSIX package.

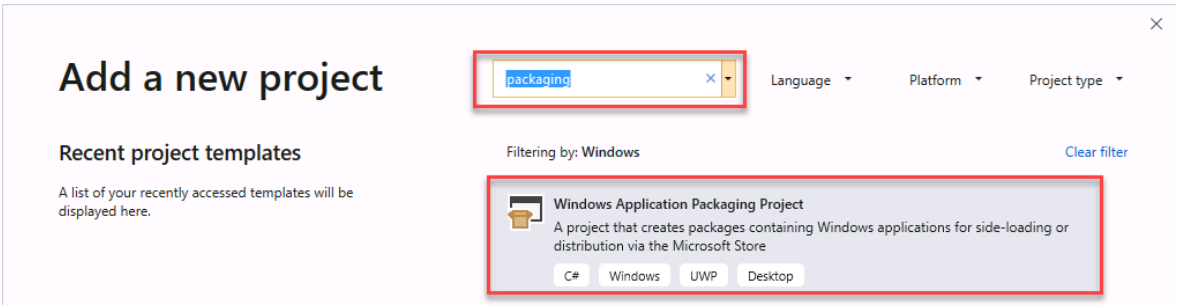
Package the application

Visual Studio 2019 provides an easy way to package a desktop application by using the Windows Application Packaging Project.

1. In **Solution Explorer**, right-click the **ContosoExpenses** solution and choose **Add -> New project**.



2. In the **Add a new project** dialog box, search for `packaging`, choose the **Windows Application Packaging Project** project template in the C# category, and click **Next**.



3. Name the new project `ContosoExpenses.Package` and click **Create**.

4. Select **Windows 10, version 1903 (10.0; Build 18362)** for both the **Target version** and **Minimum version** and click **OK**.

   The **ContosoExpenses.Package** project is added to the **ContosoExpenses** solution. This project includes a package manifest, which describes the application, and some default assets that are used for items such as the icon in the Programs menu and the tile in the Start screen. However, unlike a UWP project, the packaging project doesn't contain code. Its purpose is to package an existing desktop app.

5. In the **ContosoExpenses.Package** project, right-click the **Applications** node and choose **Add reference**. This node specifies which applications in your solution will be included in the package.

6. In the list of projects, select **ContosoExpenses.Core** and click **OK**.

7. Expand the **Applications** node and confirm that the **ContosoExpense.Core** project is referenced and highlighted in bold. This means that it will be used as a starting point for the package.

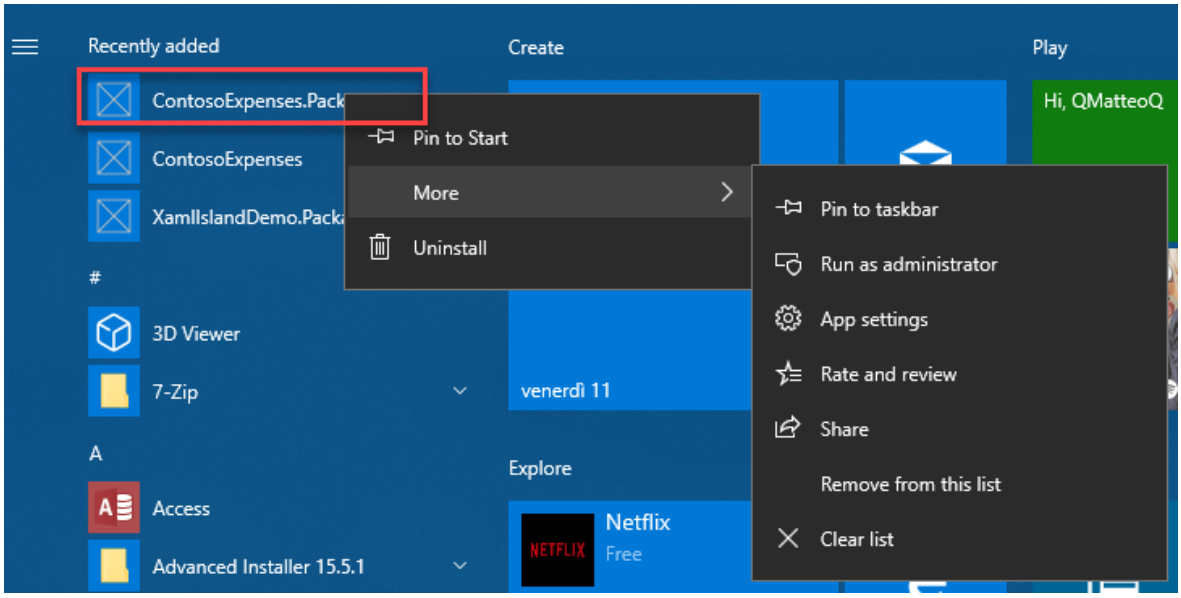
8. Right-click the **ContosoExpenses.Package** project and choose **Set As Startup Project**.

9. Press **F5** to start the packaged app in the debugger.

At this point, you can notice some changes that indicate the app is now running as packaged:

- The icon in the taskbar or in the Start menu is now the default asset that is included in every **Windows Application Packaging Project**.

- If you right-click the **ContosoExpense.Package** application listed in the Start menu, you'll notice options that are typically reserved for apps downloaded from the Microsoft Store, such as **App settings**, **Rate and review** and **Share**.

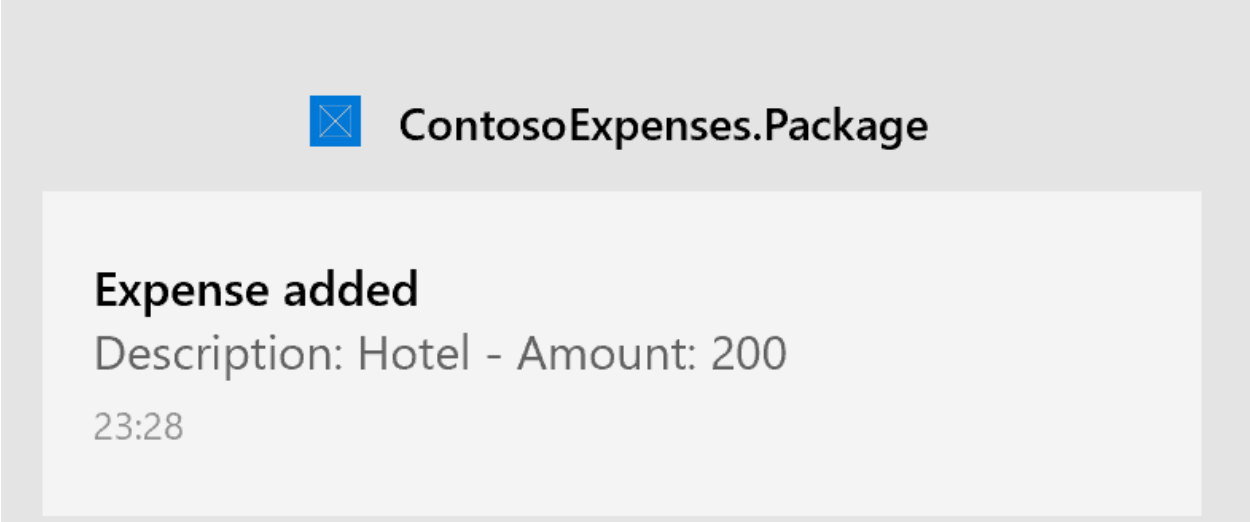


- If you want to uninstall the app, you can right-click **ContosoExpense.Package** in the Start menu and choose **Uninstall**. The app will be immediately removed, without leaving any leftover on the system.

Test the notification

Now that you have packaged the Contoso Expenses app with MSIX, you can test the notification scenario which wasn't working at the end of part 4.

1. In the Contoso Expenses app, choose an employee from the list and then click the **Add new expense** button.
2. Complete all fields in the form and press **Save**.
3. Confirm that you see an OS notification.



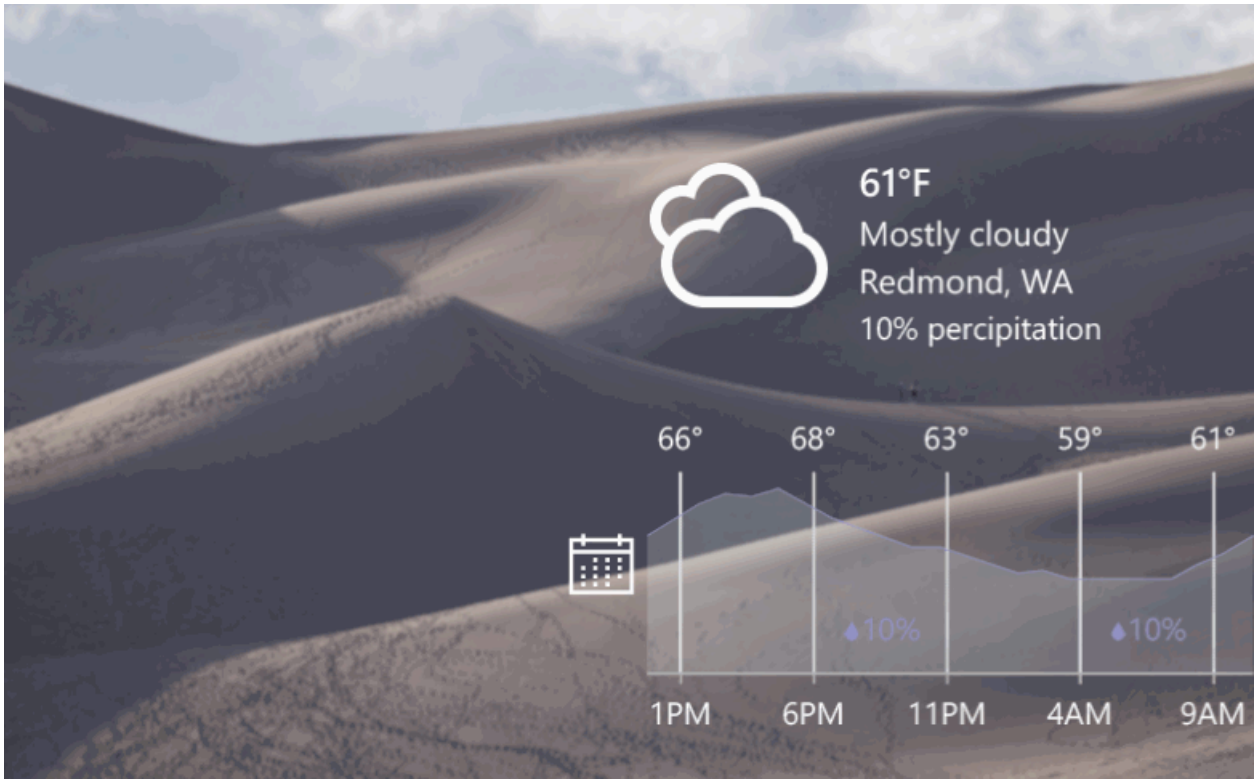
Using the Visual layer in desktop apps

Article • 08/21/2024

You can now use Windows Runtime APIs in non-UWP desktop applications to enhance the look, feel, and functionality of your WPF, Windows Forms, and C++ Win32 applications, and take advantage of the latest Windows UI features that are only available via UWP.

For many scenarios, you can use XAML islands to add modern XAML controls to your app. However, when you need to create custom experiences that go beyond the built-in controls, you can access the Visual layer APIs.

The Visual layer provides a high performance, retained-mode API for graphics, effects, and animations. It's the foundation for UI across Windows devices. UWP XAML controls are built on the Visual layer, and it enables many aspects of the Fluent Design System, such as Light, Depth, Motion, Material, and Scale.



> *User interface created with the visual layer*

Create a visually engaging user interface in any Windows app

The Visual layer lets you create engaging experiences by using lightweight compositing of custom drawn content (visuals) and applying powerful animations, effects, and

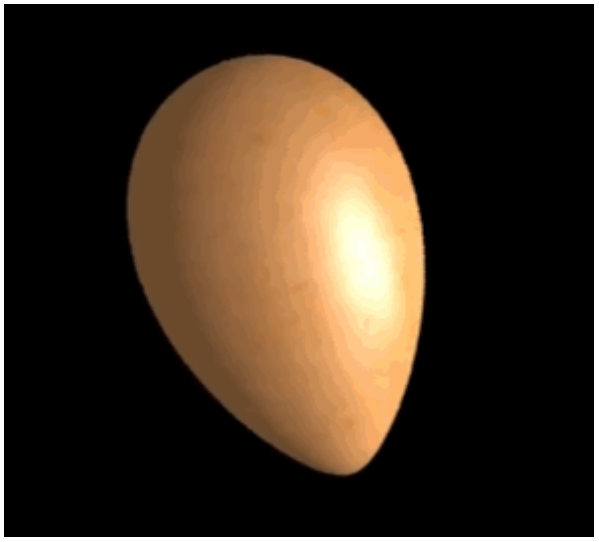
manipulations on those objects in your application. The Visual layer doesn't replace any existing UI framework; instead, it's a valuable supplement to those frameworks.

You can use the Visual layer to give your application a unique look and feel, and establish an identity that sets it apart from other applications. It also enables Fluent Design principles, which are designed to make your applications easier to use, drawing more engagement from users. For example, you can use it to create visual cues and animated screen transitions that show relationships among items on the screen.

Visual layer features

Brushes

Composition brushes let you paint UI objects with solid colors, gradients, images, videos, complex effects, and more.



> *An egg created with the Material Creator demo app.*

Effects

Composition effects include light, shadow, and a list of filter effects. They can be animated, customized, and chained, then applied directly to visuals. The SceneLightingEffect can be combined with composition lighting to create atmosphere, depth and materials.

> *Lights and material demonstrated in the Windows UI Composition sample gallery.*

Animations

Composition animations run directly in the compositor process, independent of the UI thread. This ensures smoothness and scale, so you can run large numbers of concurrent, explicit animations. In addition to familiar KeyFrame animations to drive property changes over time, you can use expressions to set up mathematical relationships between different properties, including user input. Input driven animations let you create UI that dynamically and fluidly responds to user input, which can result in higher user engagement.

> *Motion demonstrated in the Windows UI Composition sample gallery.*

Keep your existing codebase and adopt incrementally

The code in your existing applications represents a significant investment that you don't want to lose. You can migrate *islands* of content to use the Visual layer and keep the rest of the UI in its existing framework. This means you can make significant updates and enhancements to your application UI without needing to make extensive changes to your existing code base.

Samples and tutorials

Learn how to use the Visual layer in your applications by experimenting with our samples. These samples and tutorials help you get started using the Visual layer and show you how features work.

Win32

WPF

- Using the Visual layer with WPF tutorial
  - Hello Composition sample
- Visual Layer Integration sample
- Screen Capture sample

Limitations

While many Visual Layer features work the same when hosted in a desktop application as they do in a UWP app, some features do have limitations. Here are some of the limitations to be aware of:

- Effect chains rely on Win2D for the effect descriptions. The Win2D NuGet package is not supported in desktop applications, so you would need to recompile it from the source code.
- To do hit testing, you need to do bounds calculations by walking the visual tree yourself. This is the same as the Visual Layer in UWP, except in this case there's no XAML element you can easily bind to for hit testing.
- The Visual Layer does not have a primitive for rendering text.

- When two different UI technologies are used together, such as WPF and the Visual Layer, they are each responsible for drawing their own pixels on the screen, and they can't share pixels. As a result, Visual Layer content is always rendered on top of other UI content. (This is known as the *airspace* issue.) You might need to do extra coding and testing to ensure your Visual layer content resizes with the host UI and doesn't occlude other content.
- Content hosted in a desktop application doesn't automatically resize or scale for DPI. Extra steps might required to ensure your content handles DPI changes. (See the platform specific tutorials for more info.)

Using the Visual Layer with WPF

Article • 08/21/2024

You can use Windows Runtime Composition APIs (also called the Visual layer) in your Windows Presentation Foundation (WPF) apps to create modern experiences that light up for Windows users.

The complete code for this tutorial is available on GitHub: WPF HelloComposition sample.

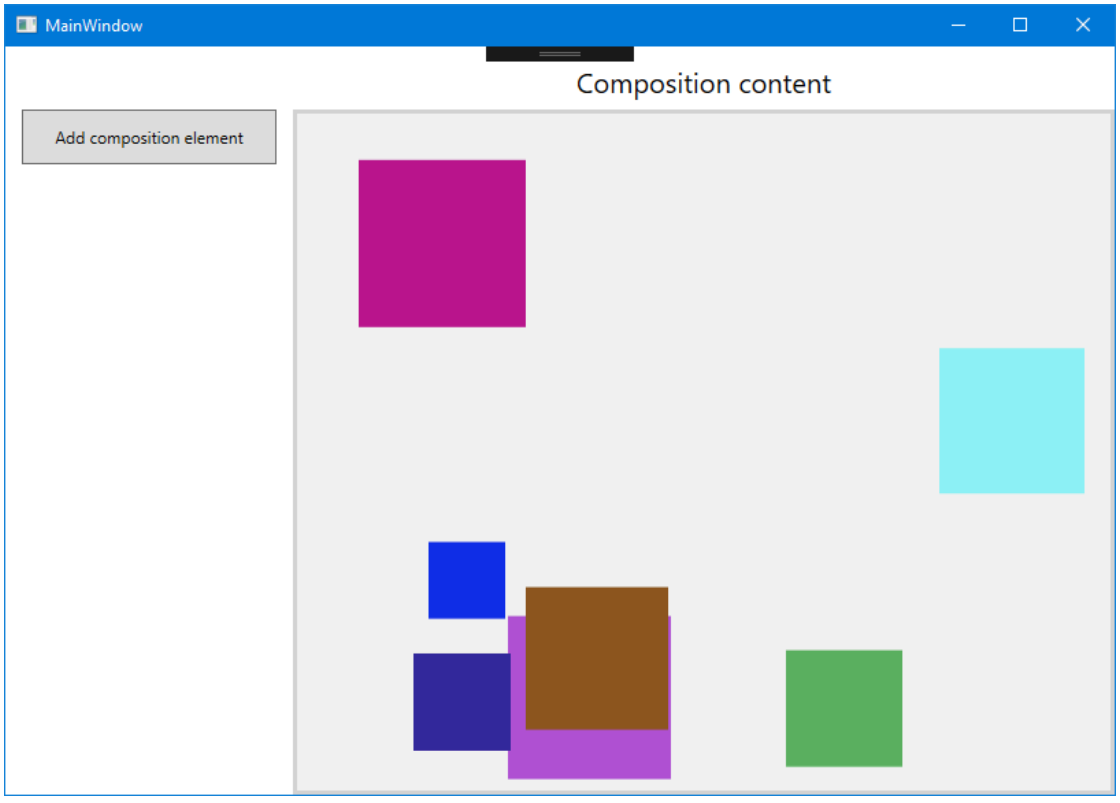
Prerequisites

The UWP XAML hosting API has these prerequisites.

- We assume that you have some familiarity with app development using WPF and UWP. For more info, see:
  - Getting Started (WPF)
  - Get started with Windows apps
  - Enhance your desktop application for Windows
- .NET Framework 4.7.2 or later
- Windows 10 version 1803 or later
- Windows 10 SDK 17134 or later

How to use Composition APIs in WPF

In this tutorial, you create a simple WPF app UI and add animated Composition elements to it. Both the WPF and Composition components are kept simple, but the interop code shown is the same regardless of the complexity of the components. The finished app looks like this.



Create a WPF project

The first step is to create the WPF app project, which includes an application definition and the XAML page for the UI.

To create a new WPF Application project in Visual C# named *HelloComposition*:

1. Open Visual Studio and select **File** > **New** > **Project**.

   The **New Project** dialog opens.

2. Under the **Installed** category, expand the **Visual C#** node, and then select **Windows Desktop**.
3. Select the **WPF App (.NET Framework)** template.
4. Enter the name *HelloComposition*, select Framework **.NET Framework 4.7.2**, then click **OK**.

   Visual Studio creates the project and opens the designer for the default application window named MainWindow.xaml.

Configure the project to use Windows Runtime APIs

To use Windows Runtime (WinRT) APIs in your WPF app, you need to configure your Visual Studio project to access the Windows Runtime. In addition, vectors are used extensively by the Composition APIs, so you need to add the references required to use vectors.

NuGet packages are available to address both of these needs. Install the latest versions of these packages to add the necessary references to your project.

- Microsoft.Windows.SDK.Contracts (Requires default package management format set to PackageReference.)
- System.Numerics.Vectors

> **Note**
>
> While we recommend using the NuGet packages to configure your project, you can add the required references manually. For more info, see Enhance your desktop application for Windows. The following table shows the files that you need to add references to.

Expand table

File	Location
System.Runtime.WindowsRuntime	C:\Windows\Microsoft.NET\Framework\v4.0.30319
Windows.Foundation.UniversalApiContract.winmd	C:\Program Files (x86)\Windows Kits\10\References\<*sdk version*>\Windows.Foundation.UniversalApiContract\<*version*>
Windows.Foundation.FoundationContract.winmd	C:\Program Files (x86)\Windows Kits\10\References\<*sdk version*>\Windows.Foundation.FoundationContract\<*version*>
System.Numerics.Vectors.dll	C:\WINDOWS\Microsoft.Net\assembly\GAC_MSIL\System.Numerics.Vectors\v4.0_4.0.0.0__b03f5f7f11d50a3a
System.Numerics.dll	C:\Program Files (x86)\Reference Assemblies\Microsoft\Framework.NETFramework\v4.7.2

Configure the project to be per-monitor DPI aware

The visual layer content you add to your app does not automatically scale to match the DPI settings of the screen it's shown on. You need to enable per-monitor DPI awareness for your app, and then make sure that the code you use to create your visual layer content takes into account the current DPI scale when the app runs. Here, we configure the project to be DPI aware. In later sections, we show how to use the DPI information to scale the visual layer content.

WPF apps are System DPI aware by default, but need to declare themselves to be per-monitor DPI aware in an app.manifest file. To turn on Windows-level per-monitor DPI awareness in the app manifest file:

1. In **Solution Explorer**, right click the *HelloComposition* project.
2. In the context menu, select **Add** > **New Item...**.
3. In the **Add New Item** dialog, select 'Application Manifest File', then click **Add**. (You can leave the default name.)
4. In the app.manifest file, find this xml and un-comment it:

```xaml
<application xmlns="urn:schemas-microsoft-com:asm.v3">
    <windowsSettings>
      <dpiAware xmlns="http://schemas.microsoft.com/SMI/2005/WindowsSettings">true</dpiAware>
```

```
    </windowsSettings>
  </application>
```

5. Add this setting after the opening `<windowsSettings>` tag:

```
XAML

      <dpiAwareness xmlns="http://schemas.microsoft.com/SMI/2016/WindowsSettings">PerMonitor</dpiAwareness>
```

6. You also need to set the **DoNotScaleForDpiChanges** setting in the App.config file.

   Open App.Config and add this xml inside the `<configuration>` element:

```
XML

<runtime>
  <AppContextSwitchOverrides value="Switch.System.Windows.DoNotScaleForDpiChanges=false"/>
</runtime>
```

> **Note**
>
> **AppContextSwitchOverrides** can only be set once. If your application already has one set, you must semicolon delimit this switch inside the value attribute.

(For more info, see the Per Monitor DPI Developer Guide and samples on GitHub.)

Create an HwndHost derived class to host composition elements

To host content you create with the visual layer, you need to create a class that derives from HwndHost. This is where you do most of the configuration for hosting Composition APIs. In this class, you use Platform Invocation Services (PInvoke) and COM Interop to bring Composition APIs into your WPF app. For more info about PInvoke and COM Interop, see Interoperating with unmanaged code.

> **Tip**
>
> If you need to, check the complete code at the end of the tutorial to make sure all the code is in the right places as you work through the tutorial.

1. Add a new class file to your project that derives from HwndHost.

   - In **Solution Explorer**, right click the *HelloComposition* project.
   - In the context menu, select **Add** > **Class...**.
   - In the **Add New Item** dialog, name the class *CompositionHost.cs*, then click **Add**.

2. In CompositionHost.cs, edit the class definition to derive from **HwndHost**.

```
C#

// Add
// using System.Windows.Interop;

namespace HelloComposition
{
    class CompositionHost : HwndHost
    {
    }
}
```

3. Add the following code and constructor to the class.

```
C#
```

```
// Add
// using Windows.UI.Composition;

IntPtr hwndHost;
int hostHeight, hostWidth;
object dispatcherQueue;
ICompositionTarget compositionTarget;

public Compositor Compositor { get; private set; }

public Visual Child
{
    set
    {
        if (Compositor == null)
        {
            InitComposition(hwndHost);
        }
        compositionTarget.Root = value;
    }
}

internal const int
  WS_CHILD = 0x40000000,
  WS_VISIBLE = 0x10000000,
  LBS_NOTIFY = 0x00000001,
  HOST_ID = 0x00000002,
  LISTBOX_ID = 0x00000001,
  WS_VSCROLL = 0x00200000,
  WS_BORDER = 0x00800000;

public CompositionHost(double height, double width)
{
    hostHeight = (int)height;
    hostWidth = (int)width;
}
```

4. Override the **BuildWindowCore** and **DestroyWindowCore** methods.

> ⓘ **Note**
>
> In BuildWindowCore, you call the *InitializeCoreDispatcher* and *InitComposition* methods. You create these methods in the next steps.

C#

```
// Add
// using System.Runtime.InteropServices;

protected override HandleRef BuildWindowCore(HandleRef hwndParent)
{
    // Create Window
    hwndHost = IntPtr.Zero;
    hwndHost = CreateWindowEx(0, "static", "",
                              WS_CHILD | WS_VISIBLE,
                              0, 0,
                              hostWidth, hostHeight,
                              hwndParent.Handle,
                              (IntPtr)HOST_ID,
                              IntPtr.Zero,
                              0);

    // Create Dispatcher Queue
    dispatcherQueue = InitializeCoreDispatcher();

    // Build Composition tree of content
    InitComposition(hwndHost);

    return new HandleRef(this, hwndHost);
}

protected override void DestroyWindowCore(HandleRef hwnd)
{
    if (compositionTarget.Root != null)
    {
```

```
        compositionTarget.Root.Dispose();
    }
    DestroyWindow(hwnd.Handle);
}
```

- CreateWindowEx and DestroyWindow require a PInvoke declaration. Place this declaration at the end of the code for the class.

C#

```
#region PInvoke declarations

[DllImport("user32.dll", EntryPoint = "CreateWindowEx", CharSet = CharSet.Unicode)]
internal static extern IntPtr CreateWindowEx(int dwExStyle,
                                             string lpszClassName,
                                             string lpszWindowName,
                                             int style,
                                             int x, int y,
                                             int width, int height,
                                             IntPtr hwndParent,
                                             IntPtr hMenu,
                                             IntPtr hInst,
                                             [MarshalAs(UnmanagedType.AsAny)] object pvParam);

[DllImport("user32.dll", EntryPoint = "DestroyWindow", CharSet = CharSet.Unicode)]
internal static extern bool DestroyWindow(IntPtr hwnd);

#endregion PInvoke declarations
```

5. Initialize a thread with a CoreDispatcher. The core dispatcher is responsible for processing window messages and dispatching events for WinRT APIs. New instances of **CoreDispatcher** must be created on a thread that has a CoreDispatcher.

   - Create a method named *InitializeCoreDispatcher* and add code to set up the dispatcher queue.

C#

```
private object InitializeCoreDispatcher()
{
    DispatcherQueueOptions options = new DispatcherQueueOptions();
    options.apartmentType = DISPATCHERQUEUE_THREAD_APARTMENTTYPE.DQTAT_COM_STA;
    options.threadType = DISPATCHERQUEUE_THREAD_TYPE.DQTYPE_THREAD_CURRENT;
    options.dwSize = Marshal.SizeOf(typeof(DispatcherQueueOptions));

    object queue = null;
    CreateDispatcherQueueController(options, out queue);
    return queue;
}
```

   - The dispatcher queue also requires a PInvoke declaration. Place this declaration inside the *PInvoke declarations* region you created in the previous step.

C#

```
//typedef enum DISPATCHERQUEUE_THREAD_APARTMENTTYPE
//{
//    DQTAT_COM_NONE,
//    DQTAT_COM_ASTA,
//    DQTAT_COM_STA
//};
internal enum DISPATCHERQUEUE_THREAD_APARTMENTTYPE
{
    DQTAT_COM_NONE = 0,
    DQTAT_COM_ASTA = 1,
    DQTAT_COM_STA = 2
};

//typedef enum DISPATCHERQUEUE_THREAD_TYPE
//{
//    DQTYPE_THREAD_DEDICATED,
//    DQTYPE_THREAD_CURRENT
//};
internal enum DISPATCHERQUEUE_THREAD_TYPE
{
    DQTYPE_THREAD_DEDICATED = 1,
```

```
    DQTYPE_THREAD_CURRENT = 2,
};

//struct DispatcherQueueOptions
//{
//    DWORD dwSize;
//    DISPATCHERQUEUE_THREAD_TYPE threadType;
//    DISPATCHERQUEUE_THREAD_APARTMENTTYPE apartmentType;
//};
[StructLayout(LayoutKind.Sequential)]
internal struct DispatcherQueueOptions
{
    public int dwSize;

    [MarshalAs(UnmanagedType.I4)]
    public DISPATCHERQUEUE_THREAD_TYPE threadType;

    [MarshalAs(UnmanagedType.I4)]
    public DISPATCHERQUEUE_THREAD_APARTMENTTYPE apartmentType;
};

//HRESULT CreateDispatcherQueueController(
//  DispatcherQueueOptions options,
//  ABI::Windows::System::IDispatcherQueueController** dispatcherQueueController
//);
[DllImport("coremessaging.dll", EntryPoint = "CreateDispatcherQueueController", CharSet = CharSet.Unicode)]
internal static extern IntPtr CreateDispatcherQueueController(DispatcherQueueOptions options,
                                        [MarshalAs(UnmanagedType.IUnknown)]
                                        out object dispatcherQueueController);
```

You now have the dispatcher queue ready and can begin to initialize and create Composition content.

6. Initialize the Compositor. The Compositor is a factory that creates a variety of types in the Windows.UI.Composition namespace spanning visuals, the effects system, and the animation system. The Compositor class also manages the lifetime of objects created from the factory.

C#

```
private void InitComposition(IntPtr hwndHost)
{
    ICompositorDesktopInterop interop;

    compositor = new Compositor();
    object iunknown = compositor as object;
    interop = (ICompositorDesktopInterop)iunknown;
    IntPtr raw;
    interop.CreateDesktopWindowTarget(hwndHost, true, out raw);

    object rawObject = Marshal.GetObjectForIUnknown(raw);
    ICompositionTarget target = (ICompositionTarget)rawObject;

    if (raw == null) { throw new Exception("QI Failed"); }
}
```

- **ICompositorDesktopInterop** and **ICompositionTarget** require COM imports. Place this code after the *CompositionHost* class, but inside the namespace declaration.

C#

```
#region COM Interop

/*
#undef INTERFACE
#define INTERFACE ICompositorDesktopInterop
    DECLARE_INTERFACE_IID_(ICompositorDesktopInterop, IUnknown, "29E691FA-4567-4DCA-B319-D0F207EB6807")
    {
        IFACEMETHOD(CreateDesktopWindowTarget)(
            _In_ HWND hwndTarget,
            _In_ BOOL isTopmost,
            _COM_Outptr_ IDesktopWindowTarget * *result
            ) PURE;
    };
*/
[ComImport]
[Guid("29E691FA-4567-4DCA-B319-D0F207EB6807")]
[InterfaceType(ComInterfaceType.InterfaceIsIUnknown)]
```

```
public interface ICompositorDesktopInterop
{
    void CreateDesktopWindowTarget(IntPtr hwndTarget, bool isTopmost, out IntPtr test);
}

//[contract(Windows.Foundation.UniversalApiContract, 2.0)]
//[exclusiveto(Windows.UI.Composition.CompositionTarget)]
//[uuid(A1BEA8BA - D726 - 4663 - 8129 - 6B5E7927FFA6)]
//interface ICompositionTarget : IInspectable
//{
//    [propget] HRESULT Root([out] [retval] Windows.UI.Composition.Visual** value);
//    [propput] HRESULT Root([in] Windows.UI.Composition.Visual* value);
//}

[ComImport]
[Guid("A1BEA8BA-D726-4663-8129-6B5E7927FFA6")]
[InterfaceType(ComInterfaceType.InterfaceIsIInspectable)]
public interface ICompositionTarget
{
    Windows.UI.Composition.Visual Root
    {
        get;
        set;
    }
}

#endregion COM Interop
```

Create a UserControl to add your content to the WPF visual tree

The last step to set up the infrastructure required to host Composition content is to add the HwndHost to the WPF visual tree.

Create a UserControl

A UserControl is a convenient way to package your code that creates and manages Composition content, and easily add the content to your XAML.

1. Add a new user control file to your project.

   - In **Solution Explorer**, right click the *HelloComposition* project.
   - In the context menu, select **Add** > **User Control...**.
   - In the **Add New Item** dialog, name the user control *CompositionHostControl.xaml*, then click **Add**.

   Both the CompositionHostControl.xaml and CompositionHostControl.xaml.cs files are created and added to your project.

2. In CompositionHostControl.xaml, replace the `<Grid> </Grid>` tags with this **Border** element, which is the XAML container that your HwndHost will go in.

   XAML

   ```
   <Border Name="CompositionHostElement"/>
   ```

In the code for the user control, you create an instance of the CompositionHost class you created in the previous step and add it as a child element of *CompositionHostElement*, the Border you created in the XAML page.

1. In CompositionHostControl.xaml.cs, add private variables for the objects you'll use in your Composition code. Add these after the class definition.

   C#

   ```
   CompositionHost compositionHost;
   Compositor compositor;
   Windows.UI.Composition.ContainerVisual containerVisual;
   DpiScale currentDpi;
   ```

2. Add a handler for the user control's **Loaded** event. This is where you set up your CompositionHost instance.

- In the constructor, hook up the event handler as shown here (`Loaded += CompositionHostControl_Loaded;`).

```
C#

public CompositionHostControl()
{
    InitializeComponent();
    Loaded += CompositionHostControl_Loaded;
}
```

- Add the event handler method with the name *CompositionHostControl_Loaded*.

```
C#

private void CompositionHostControl_Loaded(object sender, RoutedEventArgs e)
{
    // If the user changes the DPI scale setting for the screen the app is on,
    // the CompositionHostControl is reloaded. Don't redo this set up if it's
    // already been done.
    if (compositionHost is null)
    {
        currentDpi = VisualTreeHelper.GetDpi(this);

        compositionHost =
            new CompositionHost(ControlHostElement.ActualHeight, ControlHostElement.ActualWidth);
        ControlHostElement.Child = compositionHost;
        compositor = compositionHost.Compositor;
        containerVisual = compositor.CreateContainerVisual();
        compositionHost.Child = containerVisual;
    }
}
```

In this method, you set up the objects you'll use in your Composition code. Here's a quick look at what's happening.

- First, make sure the set up is only done once by checking whether an instance of CompositionHost already exists.

```
C#

// If the user changes the DPI scale setting for the screen the app is on,
// the CompositionHostControl is reloaded. Don't redo this set up if it's
// already been done.
if (compositionHost is null)
{

}
```

- Get the current DPI. This is used to properly scale your Composition elements.

```
C#

currentDpi = VisualTreeHelper.GetDpi(this);
```

- Create an instance of CompositionHost and assign it as the Child of the Border, *CompositionHostElement*.

```
C#

compositionHost =
    new CompositionHost(ControlHostElement.ActualHeight, ControlHostElement.ActualWidth);
ControlHostElement.Child = compositionHost;
```

- Get the Compositor from the CompositionHost.

```
C#

compositor = compositionHost.Compositor;
```

- Use the Compositor to create a container visual. This is the Composition container that you add your Composition elements to.

```
C#
```

```
containerVisual = compositor.CreateContainerVisual();
compositionHost.Child = containerVisual;
```

Add composition elements

With the infrastructure in place, you can now generate the Composition content you want to show.

For this example, you add code that creates and animates a simple square SpriteVisual.

1. Add a composition element. In CompositionHostControl.xaml.cs, add these methods to the CompositionHostControl class.

C#

```
// Add
// using System.Numerics;

public void AddElement(float size, float offsetX, float offsetY)
{
    var visual = compositor.CreateSpriteVisual();
    visual.Size = new Vector2(size, size);
    visual.Scale = new Vector3((float)currentDpi.DpiScaleX, (float)currentDpi.DpiScaleY, 1);
    visual.Brush = compositor.CreateColorBrush(GetRandomColor());
    visual.Offset = new Vector3(offsetX * (float)currentDpi.DpiScaleX, offsetY * (float)currentDpi.DpiScaleY, 0);

    containerVisual.Children.InsertAtTop(visual);

    AnimateSquare(visual, 3);
}

private void AnimateSquare(SpriteVisual visual, int delay)
{
    float offsetX = (float)(visual.Offset.X); // Already adjusted for DPI.

    // Adjust values for DPI scale, then find the Y offset that aligns the bottom of the square
    // with the bottom of the host container. This is the value to animate to.
    var hostHeightAdj = CompositionHostElement.ActualHeight * currentDpi.DpiScaleY;
    var squareSizeAdj = visual.Size.Y * currentDpi.DpiScaleY;
    float bottom = (float)(hostHeightAdj - squareSizeAdj);

    // Create the animation only if it's needed.
    if (visual.Offset.Y != bottom)
    {
        Vector3KeyFrameAnimation animation = compositor.CreateVector3KeyFrameAnimation();
        animation.InsertKeyFrame(1f, new Vector3(offsetX, bottom, 0f));
        animation.Duration = TimeSpan.FromSeconds(2);
        animation.DelayTime = TimeSpan.FromSeconds(delay);
        visual.StartAnimation("Offset", animation);
    }
}

private Windows.UI.Color GetRandomColor()
{
    Random random = new Random();
    byte r = (byte)random.Next(0, 255);
    byte g = (byte)random.Next(0, 255);
    byte b = (byte)random.Next(0, 255);
    return Windows.UI.Color.FromArgb(255, r, g, b);
}
```

Handle DPI changes

The code to add and animate an element takes into account the current DPI scale when elements are created, but you also need to account for DPI changes while the app is running. You can handle the HwndHost.DpiChanged event to be notified of changes and adjust your calculations based on the new DPI.

1. In the CompositionHostControl_Loaded method, after the last line, add this to hook up the DpiChanged event handler.

C#

```
compositionHost.DpiChanged += CompositionHost_DpiChanged;
```

2. Add the event handler method with the name *CompositionHostDpiChanged*. This code adjusts the scale and offset of each element, and recalculates any animations that aren't complete.

C#

```
private void CompositionHost_DpiChanged(object sender, DpiChangedEventArgs e)
{
    currentDpi = e.NewDpi;
    Vector3 newScale = new Vector3((float)e.NewDpi.DpiScaleX, (float)e.NewDpi.DpiScaleY, 1);

    foreach (SpriteVisual child in containerVisual.Children)
    {
        child.Scale = newScale;
        var newOffsetX = child.Offset.X * ((float)e.NewDpi.DpiScaleX / (float)e.OldDpi.DpiScaleX);
        var newOffsetY = child.Offset.Y * ((float)e.NewDpi.DpiScaleY / (float)e.OldDpi.DpiScaleY);
        child.Offset = new Vector3(newOffsetX, newOffsetY, 1);

        // Adjust animations for DPI change.
        AnimateSquare(child, 0);
    }
}
```

Add the user control to your XAML page

Now, you can add the user control to your XAML UI.

1. In MainWindow.xaml, set the Window Height to 600 and the Width to 840.

2. Add the XAML for the UI. In MainWindow.xaml, add this XAML between the root `<Grid> </Grid>` tags.

XAML

```
<Grid.ColumnDefinitions>
    <ColumnDefinition Width="210"/>
    <ColumnDefinition Width="600"/>
    <ColumnDefinition/>
</Grid.ColumnDefinitions>
<Grid.RowDefinitions>
    <RowDefinition Height="46"/>
    <RowDefinition/>
</Grid.RowDefinitions>
<Button Content="Add composition element" Click="Button_Click"
        Grid.Row="1" Margin="12,0"
        VerticalAlignment="Top" Height="40"/>
<TextBlock Text="Composition content" FontSize="20"
           Grid.Column="1" Margin="0,12,0,4"
           HorizontalAlignment="Center"/>
<local:CompositionHostControl x:Name="CompositionHostControl1"
                              Grid.Row="1" Grid.Column="1"
                              VerticalAlignment="Top"
                              Width="600" Height="500"
                              BorderBrush="LightGray"
                              BorderThickness="3"/>
```

3. Handle the button click to create new elements. (The Click event is already hooked up in the XAML.)

   In MainWindow.xaml.cs, add this *Button_Click* event handler method. This code calls *CompositionHost.AddElement* to create a new element with a randomly generated size and offset.

C#

```
// Add
// using System;

private void Button_Click(object sender, RoutedEventArgs e)
{
    Random random = new Random();
    float size = random.Next(50, 150);
    float offsetX = random.Next(0, (int)(CompositionHostControl1.ActualWidth - size));
    float offsetY = random.Next(0, (int)(CompositionHostControl1.ActualHeight/2 - size));
    CompositionHostControl1.AddElement(size, offsetX, offsetY);
}
```

You can now build and run your WPF app. If you need to, check the complete code at the end of the tutorial to make sure all the code is in the right places.

When you run the app and click the button, you should see animated squares added to the UI.

Next steps

For a more complete example that builds on the same infrastructure, see the WPF Visual layer integration sample on GitHub.

Complete code

Here's the complete code for this tutorial.

MainWindow.xaml

XAML

```
<Window x:Class="HelloComposition.MainWindow"
        xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
        xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
        xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
        xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
        xmlns:local="clr-namespace:HelloComposition"
        mc:Ignorable="d"
        Title="MainWindow" Height="600" Width="840">
    <Grid>
        <Grid.ColumnDefinitions>
            <ColumnDefinition Width="210"/>
            <ColumnDefinition Width="600"/>
            <ColumnDefinition/>
        </Grid.ColumnDefinitions>
        <Grid.RowDefinitions>
            <RowDefinition Height="46"/>
            <RowDefinition/>
        </Grid.RowDefinitions>
        <Button Content="Add composition element" Click="Button_Click"
                Grid.Row="1" Margin="12,0"
                VerticalAlignment="Top" Height="40"/>
        <TextBlock Text="Composition content" FontSize="20"
                   Grid.Column="1" Margin="0,12,0,4"
                   HorizontalAlignment="Center"/>
        <local:CompositionHostControl x:Name="CompositionHostControl1"
                                      Grid.Row="1" Grid.Column="1"
                                      VerticalAlignment="Top"
                                      Width="600" Height="500"
                                      BorderBrush="LightGray" BorderThickness="3"/>
    </Grid>
</Window>
```

MainWindow.xaml.cs

C#

```
using System;
using System.Windows;

namespace HelloComposition
{
    /// <summary>
```

```
    /// Interaction logic for MainWindow.xaml
    /// </summary>
    public partial class MainWindow : Window
    {
        public MainWindow()
        {
            InitializeComponent();
        }

        private void Button_Click(object sender, RoutedEventArgs e)
        {
            Random random = new Random();
            float size = random.Next(50, 150);
            float offsetX = random.Next(0, (int)(CompositionHostControl1.ActualWidth - size));
            float offsetY = random.Next(0, (int)(CompositionHostControl1.ActualHeight/2 - size));
            CompositionHostControl1.AddElement(size, offsetX, offsetY);
        }
    }
}
```

CompositionHostControl.xaml

XAML

```
<UserControl x:Class="HelloComposition.CompositionHostControl"
             xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
             xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
             xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
             xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
             xmlns:local="clr-namespace:HelloComposition"

Using the Visual Layer with Windows Forms

Article • 08/21/2024

You can use Windows Runtime Composition APIs (also called the Visual layer) in your Windows Forms apps to create modern experiences that light up for Windows users.

The complete code for this tutorial is available on GitHub: Windows Forms HelloComposition sample.

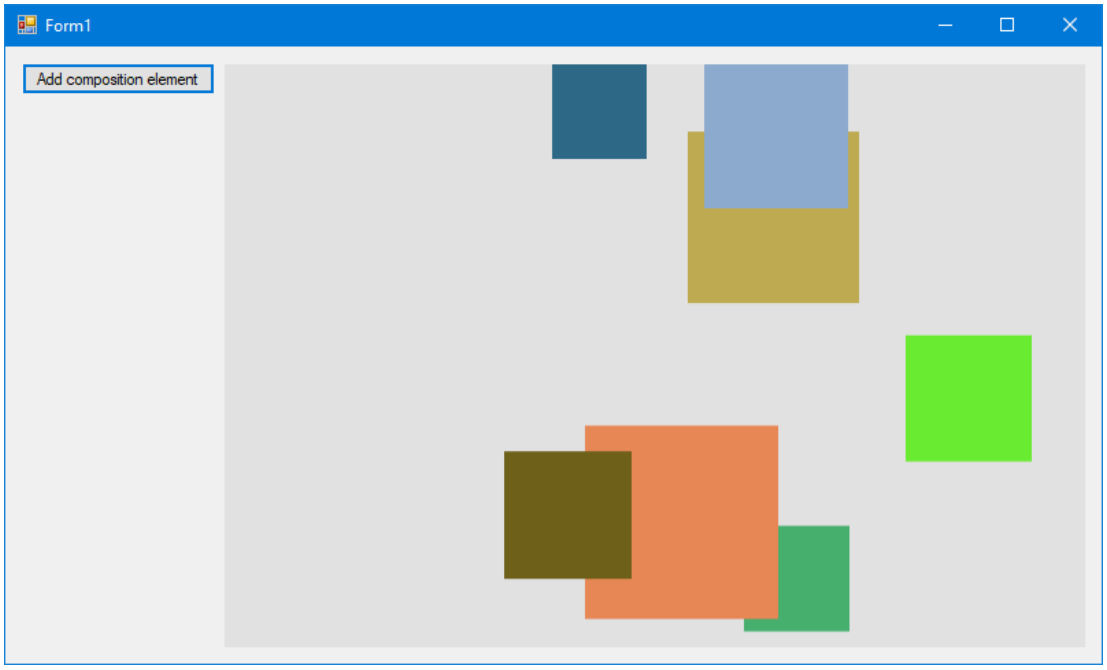
Prerequisites

The UWP hosting API has these prerequisites.

- We assume that you have some familiarity with app development using Windows Forms and UWP. For more info, see:
  - Getting Started with Windows Forms
  - Get started with Windows apps
  - Enhance your desktop application for Windows
- .NET Framework 4.7.2 or later
- Windows 10 version 1803 or later
- Windows 10 SDK 17134 or later

How to use Composition APIs in Windows Forms

In this tutorial, you create a simple Windows Forms UI and add animated Composition elements to it. Both the Windows Forms and Composition components are kept simple, but the interop code shown is the same regardless of the complexity of the components. The finished app looks like this.



Create a Windows Forms project

The first step is to create the Windows Forms app project, which includes an application definition and the main form for the UI.

To create a new Windows Forms Application project in Visual C# named *HelloComposition*:

1. Open Visual Studio and select **File** > **New** > **Project**.
   The **New Project** dialog opens.
2. Under the **Installed** category, expand the **Visual C#** node, and then select **Windows Desktop**.
3. Select the **Windows Forms App (.NET Framework)** template.
4. Enter the name *HelloComposition,* select Framework **.NET Framework 4.7.2**, then click **OK**.

Visual Studio creates the project and opens the designer for the default application window named Form1.cs.

Configure the project to use Windows Runtime APIs

To use Windows Runtime (WinRT) APIs in your Windows Forms app, you need to configure your Visual Studio project to access the Windows Runtime. In addition, vectors are used extensively by the Composition APIs, so you need to add the references required to use vectors.

NuGet packages are available to address both of these needs. Install the latest versions of these packages to add the necessary references to your project.

- Microsoft.Windows.SDK.Contracts (Requires default package management format set to PackageReference.)
- System.Numerics.Vectors

> **Note**
>
> While we recommend using the NuGet packages to configure your project, you can add the required references manually. For more info, see **Enhance your desktop application for Windows**. The following table shows the files that you need to add references to.

Expand table

File	Location
System.Runtime.WindowsRuntime	C:\Windows\Microsoft.NET\Framework\v4.0.30319
Windows.Foundation.UniversalApiContract.winmd	C:\Program Files (x86)\Windows Kits\10\References\<*sdk version*>\Windows.Foundation.UniversalApiContract\<*version*>
Windows.Foundation.FoundationContract.winmd	C:\Program Files (x86)\Windows Kits\10\References\<*sdk version*>\Windows.Foundation.FoundationContract\<*version*>
System.Numerics.Vectors.dll	C:\WINDOWS\Microsoft.Net\assembly\GAC_MSIL\System.Numerics.Vectors\v4.0_4.0.0.0__b03f5f7f11d50a3a
System.Numerics.dll	C:\Program Files (x86)\Reference Assemblies\Microsoft\Framework.NETFramework\v4.7.2

Create a custom control to manage interop

To host content you create with the visual layer, you create a custom control derived from Control. This control gives you access to a window Handle, which you need in order to create the container for your visual layer content.

This is where you do most of the configuration for hosting Composition APIs. In this control, you use Platform Invocation Services (PInvoke) and COM Interop to bring Composition APIs into your Windows Forms app. For more info about PInvoke and COM Interop, see Interoperating with unmanaged code.

> **Tip**
>
> If you need to, check the complete code at the end of the tutorial to make sure all the code is in the right places as you work through the tutorial.

1. Add a new custom control file to your project that derives from Control.
   - In **Solution Explorer**, right click the *HelloComposition* project.
   - In the context menu, select **Add** > **New Item...**.
   - In the **Add New Item** dialog, select **Custom Control**.
   - Name the control *CompositionHost.cs*, then click **Add**. CompositionHost.cs opens in the Design view.
2. Switch to code view for CompositionHost.cs and add the following code to the class.

```
C#
```

```
// Add
// using Windows.UI.Composition;

IntPtr hwndHost;
object dispatcherQueue;
protected ContainerVisual containerVisual;
```

```
protected Compositor compositor;

private ICompositionTarget compositionTarget;

public Visual Child
{
    set
    {
        if (compositor == null)
        {
            InitComposition(hwndHost);
        }
        compositionTarget.Root = value;
    }
}
```

3. Add code to the constructor.

   In the constructor, you call the *InitializeCoreDispatcher* and *InitComposition* methods. You create these methods in the next steps.

```
C#

public CompositionHost()
{
    InitializeComponent();

    // Get the window handle.
    hwndHost = Handle;

    // Create dispatcher queue.
    dispatcherQueue = InitializeCoreDispatcher();

    // Build Composition tree of content.
    InitComposition(hwndHost);
}
```

4. Initialize a thread with a CoreDispatcher. The core dispatcher is responsible for processing window messages and dispatching events for WinRT APIs. New instances of **Compositor** must be created on a thread that has a CoreDispatcher.

   - Create a method named *InitializeCoreDispatcher* and add code to set up the dispatcher queue.

```
C#

// Add
// using System.Runtime.InteropServices;

private object InitializeCoreDispatcher()
{
    DispatcherQueueOptions options = new DispatcherQueueOptions();
    options.apartmentType = DISPATCHERQUEUE_THREAD_APARTMENTTYPE.DQTAT_COM_STA;
    options.threadType = DISPATCHERQUEUE_THREAD_TYPE.DQTYPE_THREAD_CURRENT;
    options.dwSize = Marshal.SizeOf(typeof(DispatcherQueueOptions));

    object queue = null;
    CreateDispatcherQueueController(options, out queue);
    return queue;
}
```

   - The dispatcher queue requires a PInvoke declaration. Place this declaration at the end of the code for the class. (We place this code inside a region to keep the class code tidy.)

```
C#

#region PInvoke declarations

//typedef enum DISPATCHERQUEUE_THREAD_APARTMENTTYPE
//{
//    DQTAT_COM_NONE,
//    DQTAT_COM_ASTA,
//    DQTAT_COM_STA
//};
internal enum DISPATCHERQUEUE_THREAD_APARTMENTTYPE
{
    DQTAT_COM_NONE = 0,
    DQTAT_COM_ASTA = 1,
```

```
    DQTAT_COM_STA = 2
};

//typedef enum DISPATCHERQUEUE_THREAD_TYPE
//{
//    DQTYPE_THREAD_DEDICATED,
//    DQTYPE_THREAD_CURRENT
//};
internal enum DISPATCHERQUEUE_THREAD_TYPE
{
    DQTYPE_THREAD_DEDICATED = 1,
    DQTYPE_THREAD_CURRENT = 2,
};

//struct DispatcherQueueOptions
//{
//    DWORD dwSize;
//    DISPATCHERQUEUE_THREAD_TYPE threadType;
//    DISPATCHERQUEUE_THREAD_APARTMENTTYPE apartmentType;
//};
[StructLayout(LayoutKind.Sequential)]
internal struct DispatcherQueueOptions
{
    public int dwSize;

    [MarshalAs(UnmanagedType.I4)]
    public DISPATCHERQUEUE_THREAD_TYPE threadType;

    [MarshalAs(UnmanagedType.I4)]
    public DISPATCHERQUEUE_THREAD_APARTMENTTYPE apartmentType;
};

//HRESULT CreateDispatcherQueueController(
//  DispatcherQueueOptions options,
//  ABI::Windows::System::IDispatcherQueueController** dispatcherQueueController
//);
[DllImport("coremessaging.dll", EntryPoint = "CreateDispatcherQueueController", CharSet = CharSet.Unicode)]
internal static extern IntPtr CreateDispatcherQueueController(DispatcherQueueOptions options,
                                        [MarshalAs(UnmanagedType.IUnknown)]
                                        out object dispatcherQueueController);

#endregion PInvoke declarations
```

You now have the dispatcher queue ready and can begin to initialize and create Composition content.

5. Initialize the Compositor. The Compositor is a factory that creates a variety of types in the Windows.UI.Composition namespace spanning the visual layer, effects system, and animation system. The Compositor class also manages the lifetime of objects created from the factory.

C#

```
private void InitComposition(IntPtr hwndHost)
{
    ICompositorDesktopInterop interop;

    compositor = new Compositor();
    object iunknown = compositor as object;
    interop = (ICompositorDesktopInterop)iunknown;
    IntPtr raw;
    interop.CreateDesktopWindowTarget(hwndHost, true, out raw);

    object rawObject = Marshal.GetObjectForIUnknown(raw);
    compositionTarget = (ICompositionTarget)rawObject;

    if (raw == null) { throw new Exception("QI Failed"); }

    containerVisual = compositor.CreateContainerVisual();
    Child = containerVisual;
}
```

- **ICompositorDesktopInterop** and **ICompositionTarget** require COM imports. Place this code after the *CompositionHost* class, but inside the namespace declaration.

C#

```
#region COM Interop

/*
#undef INTERFACE
#define INTERFACE ICompositorDesktopInterop
    DECLARE_INTERFACE_IID_(ICompositorDesktopInterop, IUnknown, "29E691FA-4567-4DCA-B319-D0F207EB6807")
    {
        IFACEMETHOD(CreateDesktopWindowTarget)(
            _In_ HWND hwndTarget,
            _In_ BOOL isTopmost,
            _COM_Outptr_ IDesktopWindowTarget * *result
            ) PURE;
    };
*/
[ComImport]
[Guid("29E691FA-4567-4DCA-B319-D0F207EB6807")]
[InterfaceType(ComInterfaceType.InterfaceIsIUnknown)]
public interface ICompositorDesktopInterop
{
    void CreateDesktopWindowTarget(IntPtr hwndTarget, bool isTopmost, out IntPtr test);
}

//[contract(Windows.Foundation.UniversalApiContract, 2.0)]
//[exclusiveto(Windows.UI.Composition.CompositionTarget)]
//[uuid(A1BEA8BA - D726 - 4663 - 8129 - 6B5E7927FFA6)]
//interface ICompositionTarget : IInspectable
//{
//    [propget] HRESULT Root([out] [retval] Windows.UI.Composition.Visual** value);
//    [propput] HRESULT Root([in] Windows.UI.Composition.Visual* value);
//}

[ComImport]
[Guid("A1BEA8BA-D726-4663-8129-6B5E7927FFA6")]
[InterfaceType(ComInterfaceType.InterfaceIsIInspectable)]
public interface ICompositionTarget
{
    Windows.UI.Composition.Visual Root
    {
        get;
        set;
    }
}

#endregion COM Interop
```

Create a custom control to host composition elements

It's a good idea to put the code that generates and manages your composition elements in a separate control that derives from CompositionHost. This keeps the interop code you created in the CompositionHost class reusable.

Here, you create a custom control derived from CompositionHost. This control is added to the Visual Studio toolbox so you can add it to your form.

1. Add a new custom control file to your project that derives from CompositionHost.

   - In **Solution Explorer**, right click the *HelloComposition* project.
   - In the context menu, select **Add** > **New Item...**.
   - In the **Add New Item** dialog, select **Custom Control**.
   - Name the control *CompositionHostControl.cs*, then click **Add**. CompositionHostControl.cs opens in the Design view.

2. In the Properties pane for CompositionHostControl.cs design view, set the **BackColor** property to **ControlLight**.

   Setting the background color is optional. We do it here so you can see your custom control against the form background.

3. Switch to code view for CompositionHostControl.cs and update the class declaration to derive from CompositionHost.

   ```
   C#

   class CompositionHostControl : CompositionHost
   ```

4. Update the constructor to call the base constructor.

```
C#

public CompositionHostControl() : base()
{

}
```

Add composition elements

With the infrastructure in place, you can now add Composition content to the app UI.

For this example, you add code to the CompositionHostControl class that creates and animates a simple SpriteVisual.

1. Add a composition element.

   In CompositionHostControl.cs, add these methods to the CompositionHostControl class.

```
C#

// Add
// using Windows.UI.Composition;

public void AddElement(float size, float offsetX, float offsetY)
{
    var visual = compositor.CreateSpriteVisual();
    visual.Size = new Vector2(size, size); // Requires references
    visual.Brush = compositor.CreateColorBrush(GetRandomColor());
    visual.Offset = new Vector3(offsetX, offsetY, 0);
    containerVisual.Children.InsertAtTop(visual);

    AnimateSquare(visual, 3);
}

private void AnimateSquare(SpriteVisual visual, int delay)
{
    float offsetX = (float)(visual.Offset.X);
    Vector3KeyFrameAnimation animation = compositor.CreateVector3KeyFrameAnimation();
    float bottom = Height - visual.Size.Y;
    animation.InsertKeyFrame(1f, new Vector3(offsetX, bottom, 0f));
    animation.Duration = TimeSpan.FromSeconds(2);
    animation.DelayTime = TimeSpan.FromSeconds(delay);
    visual.StartAnimation("Offset", animation);
}

private Windows.UI.Color GetRandomColor()
{
    Random random = new Random();
    byte r = (byte)random.Next(0, 255);
    byte g = (byte)random.Next(0, 255);
    byte b = (byte)random.Next(0, 255);
    return Windows.UI.Color.FromArgb(255, r, g, b);
}
```

Add the control to your form

Now that you have a custom control to host Composition content, you can add it to the app UI. Here, you add an instance of the CompositionHostControl you created in the previous step. CompositionHostControl is automatically added to the Visual Studio toolbox under ***project name*** **Components**.

1. In Form1.CS design view, add a Button to the UI.

   - Drag a Button from the toolbox onto Form1. Place it in the upper left corner of the form. (See the image at the start of the tutorial to check the placement of the controls.)
   - In the Properties pane, change the **Text** property from *button1* to *Add composition element*.
   - Resize the Button so that all the text shows.

   (For more info, see How to: Add Controls to Windows Forms.)

2. Add a CompositionHostControl to the UI.

- Drag a CompositionHostControl from the toolbox onto Form1. Place it to the right of the Button.
- Resize the CompositionHost so that it fills the remainder of the form.

3. Handle the button click event.

   - In the Properties pane, click the lightning bolt to switch to the Events view.
   - In the events list, select the **Click** event, type *Button_Click*, and press Enter.
   - This code is added in Form1.cs:

```
C#

private void Button_Click(object sender, EventArgs e)
{

}
```

4. Add code to the button click handler to create new elements.

   - In Form1.cs, add code to the *Button_Click* event handler you created previously. This code calls *CompositionHostControl1.AddElement* to create a new element with a randomly generated size and offset. (The instance of CompositionHostControl was automatically named *compositionHostControl1* when you dragged it onto the form.)

```
C#

// Add
// using System;

private void Button_Click(object sender, RoutedEventArgs e)
{
    Random random = new Random();
    float size = random.Next(50, 150);
    float offsetX = random.Next(0, (int)(compositionHostControl1.Width - size));
    float offsetY = random.Next(0, (int)(compositionHostControl1.Height/2 - size));
    compositionHostControl1.AddElement(size, offsetX, offsetY);
}
```

You can now build and run your Windows Forms app. When you click the button, you should see animated squares added to the UI.

Next steps

For a more complete example that builds on the same infrastructure, see the Windows Forms Visual layer integration sample on GitHub.

Complete code

Here's the complete code for this tutorial.

Form1.cs

```
C#

using System;
using System.Windows.Forms;

namespace HelloComposition
{
```

```
    public partial class Form1 : Form
    {
        public Form1()
        {
            InitializeComponent();
        }

        private void Button_Click(object sender, EventArgs e)
        {
            Random random = new Random();
            float size = random.Next(50, 150);
            float offsetX = random.Next(0, (int)(compositionHostControl1.Width - size));
            float offsetY = random.Next(0, (int)(compositionHostControl1.Height/2 - size));
            compositionHostControl1.AddElement(size, offsetX, offsetY);
        }
    }
}
```

CompositionHostControl.cs

C#

```
using System;
using System.Numerics;
using Windows.UI.Composition;

namespace HelloComposition
{
    class CompositionHostControl : CompositionHost
    {
        public CompositionHostControl() : base()
        {

        }

        public void AddElement(float size, float offsetX, float offsetY)
        {
            var visual = compositor.CreateSpriteVisual();
            visual.Size = new Vector2(size, size); // Requires references
            visual.Brush = compositor.CreateColorBrush(GetRandomColor());
            visual.Offset = new Vector3(offsetX, offsetY, 0);
            containerVisual.Children.InsertAtTop(visual);

            AnimateSquare(visual, 3);
        }

        private void AnimateSquare(SpriteVisual visual, int delay)
        {
            float offsetX = (float)(visual.Offset.X);
            Vector3KeyFrameAnimation animation = compositor.CreateVector3KeyFrameAnimation();
            float bottom = Height - visual.Size.Y;
            animation.InsertKeyFrame(1f, new Vector3(offsetX, bottom, 0f));
            animation.Duration = TimeSpan.FromSeconds(2);
            animation.DelayTime = TimeSpan.FromSeconds(delay);
            visual.StartAnimation("Offset", animation);
        }

        private Windows.UI.Color GetRandomColor()
        {
            Random random = new Random();
            byte r = (byte)random.Next(0, 255);
            byte g = (byte)random.Next(0, 255);
            byte b = (byte)random.Next(0, 255);
            return Windows.UI.Color.FromArgb(255, r, g, b);
        }
    }
}
```

Using the Visual Layer with Win32

Article • 08/21/2024

You can use Windows Runtime Composition APIs (also called the Visual layer) in your Win32 apps to create modern experiences that light up for Windows users.

The complete code for this tutorial is available on GitHub: Win32 HelloComposition sample.

Universal Windows Applications that need precise control over their UI composition have access to the Windows.UI.Composition namespace to exert fine grained control over how their UI is composed and rendered. This composition API is not limited to UWP apps, however. Win32 desktop applications can take advantage of the modern composition systems in UWP and Windows.

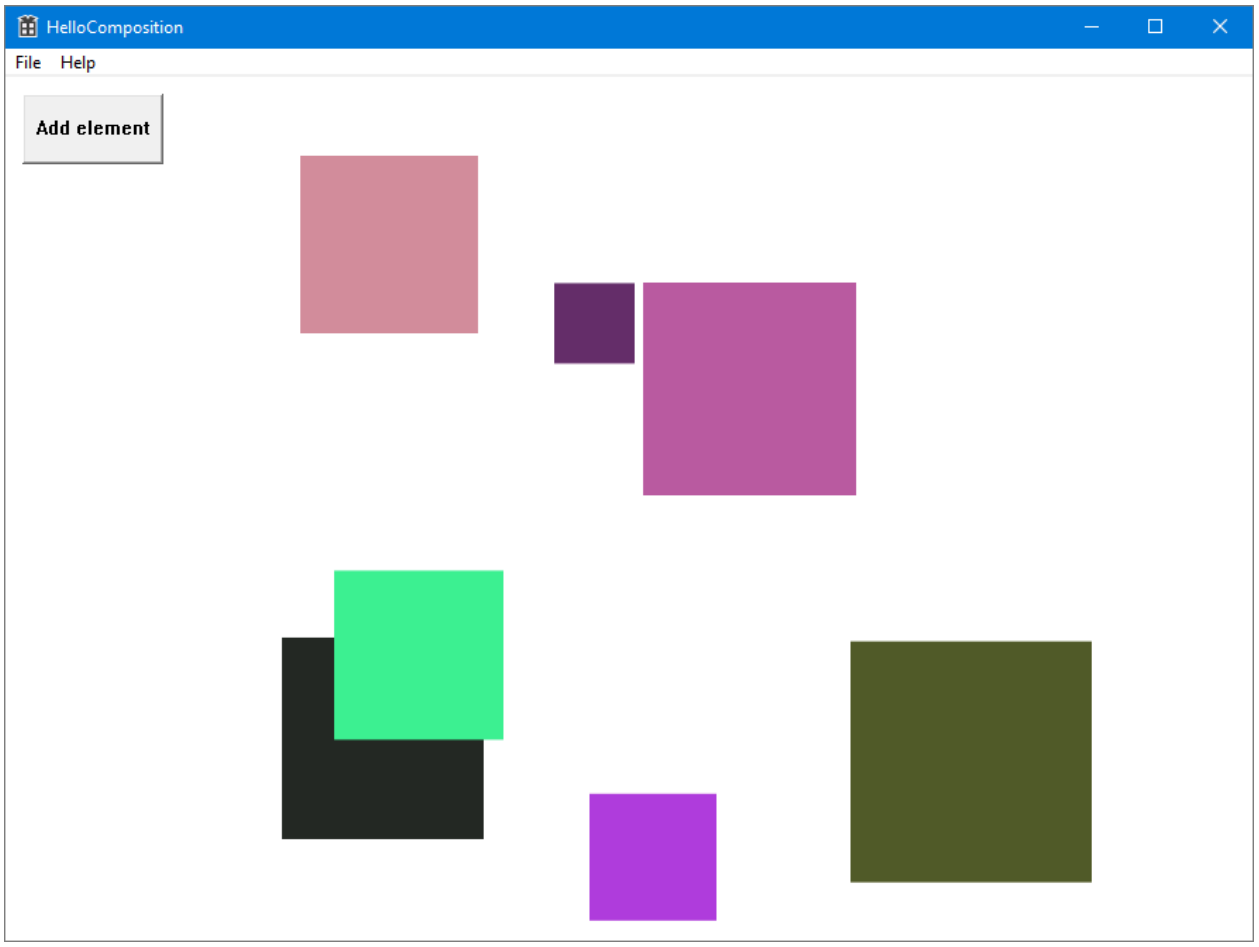
Prerequisites

The UWP hosting API has these prerequisites.

- We assume that you have some familiarity with app development using Win32 and UWP. For more info, see:
  - Get Started with Win32 and C++
  - Get started with Windows apps
  - Enhance your desktop application for Windows
- Windows 10 version 1803 or later
- Windows 10 SDK 17134 or later

How to use Composition APIs from a Win32 desktop application

In this tutorial, you create a simple Win32 C++ app and add UWP Composition elements to it. The focus is on correctly configuring the project, creating the interop code, and drawing something simple using Windows Composition APIs. The finished app looks like this.



Create a C++ Win32 project in Visual Studio

The first step is to create the Win32 app project in Visual Studio.

To create a new Win32 Application project in C++ named *HelloComposition*:

1. Open Visual Studio and select **File** > **New** > **Project**.

   The **New Project** dialog opens.

2. Under the **Installed** category, expand the **Visual C++** node, and then select **Windows Desktop**.

3. Select the **Windows Desktop Application** template.

4. Enter the name *HelloComposition*, then click **OK**.

   Visual Studio creates the project and opens the editor for the main app file.

Configure the project to use Windows Runtime APIs

To use Windows Runtime (WinRT) APIs in your Win32 app, we use C++/WinRT. You need to configure your Visual Studio project to add C++/WinRT support.

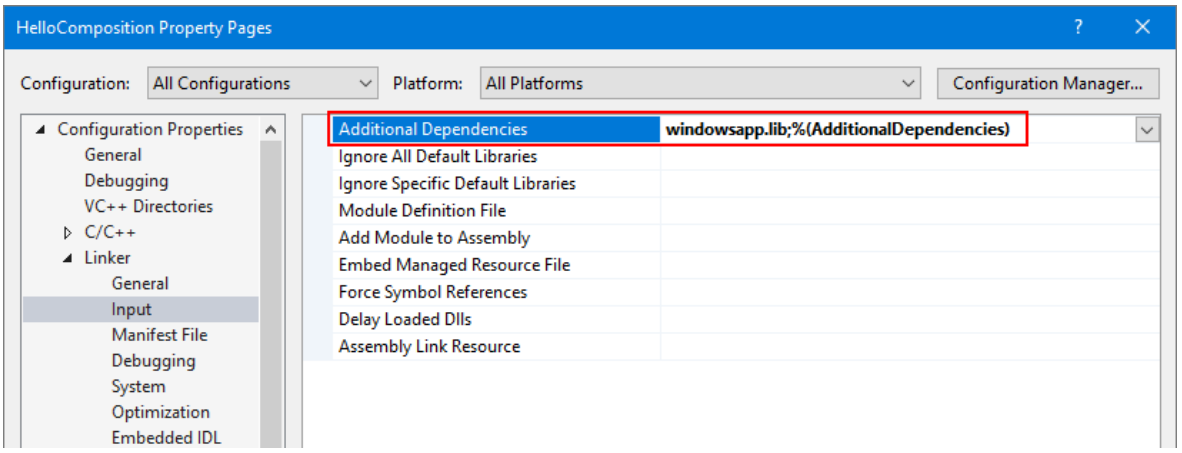
(For details, see Get started with C++/WinRT - Modify a Windows Desktop application project to add C++/WinRT support).

1. From the **Project** menu, open the project properties (*HelloComposition Properties*) and ensure the following settings are set to the specified values:

    - For **Configuration**, select *All Configurations*. For **Platform**, select *All Platforms*.
    - **Configuration Properties** > **General** > **Windows SDK Version** = *10.0.17763.0* or greater

    - **C/C++** > **Language** > **C++ Language Standard** = *ISO C++ 17 Standard (/stf:c++17)*

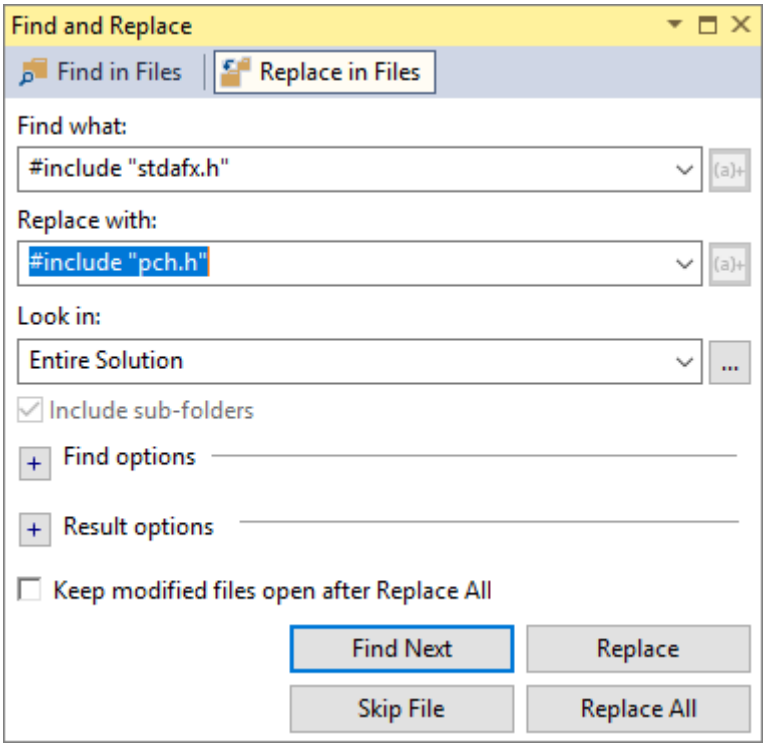
    - **Linker** > **Input** > **Additional Dependencies** must include "*windowsapp.lib*". If it's not included in the list, add it.



2. Update the precompiled header

- Rename `stdafx.h` and `stdafx.cpp` to `pch.h` and `pch.cpp`, respectively.
- Set project property **C/C++** > **Precompiled Headers** > **Precompiled Header File** to *pch.h*.
- Find and replace `#include "stdafx.h"` with `#include "pch.h"` in all files.

  (**Edit** > **Find and Replace** > **Find in Files**)



- In `pch.h`, include `winrt/base.h` and `unknwn.h`.

C++/WinRT

```
// reference additional headers your program requires here
#include <unknwn.h>
#include <winrt/base.h>
```

It's a good idea to build the project at this point to make sure there are no errors before going on.

Create a class to host composition elements

To host content you create with the visual layer, create a class (*CompositionHost*) to manage interop and create composition elements. This is where you do most of the configuration for hosting Composition APIs, including:

- getting a Compositor, which creates and manages objects in the Windows.UI.Composition namespace.
- creating a DispatcherQueueController/DispatcherQueue to manage tasks for the WinRT APIs.
- creating a DesktopWindowTarget and Composition container to display the composition objects.

We make this class a singleton to avoid threading issues. For example, you can only create one dispatcher queue per thread, so instantiating a second instance of CompositionHost on the same thread would cause an error.

> **Tip**
>
> If you need to, check the complete code at the end of the tutorial to make sure all the code is in the right places as you work through the tutorial.

1. Add a new class file to your project.

    - In **Solution Explorer**, right click the *HelloComposition* project.
    - In the context menu, select **Add** > **Class...**.
    - In the **Add Class** dialog, name the class *CompositionHost.cs*, then click **Add**.

2. Include headers and *usings* required for composition interop.

    - In CompositionHost.h, add these *includes* at the top of the file.

    C++/WinRT

    ```
    #pragma once
    #include <winrt/Windows.UI.Composition.Desktop.h>
    #include <windows.ui.composition.interop.h>
    #include <DispatcherQueue.h>
    ```

- In CompositionHost.cpp, add these *usings* at the top of the file, after any *includes*.

C++/WinRT

```
using namespace winrt;
using namespace Windows::System;
using namespace Windows::UI;
using namespace Windows::UI::Composition;
using namespace Windows::UI::Composition::Desktop;
using namespace Windows::Foundation::Numerics;
```

3. Edit the class to use the singleton pattern.

- In CompositionHost.h, make the constructor private.
- Declare a public static *GetInstance* method.

C++/WinRT

```
class CompositionHost
{
public:
    ~CompositionHost();
    static CompositionHost* GetInstance();

private:
    CompositionHost();
};
```

- In CompositionHost.cpp, add the definition of the *GetInstance* method.

C++/WinRT

```
CompositionHost* CompositionHost::GetInstance()
{
    static CompositionHost instance;
    return &instance;
}
```

4. In CompositionHost.h, declare private member variables for the Compositor, DispatcherQueueController, and DesktopWindowTarget.

C++/WinRT

```
winrt::Windows::UI::Composition::Compositor m_compositor{ nullptr };
winrt::Windows::System::DispatcherQueueController
m_dispatcherQueueController{ nullptr };
```

```
winrt::Windows::UI::Composition::Desktop::DesktopWindowTarget m_target{
nullptr };
```

5. Add a public method to initialize the composition interop objects.

> **Note**
>
> In *Initialize*, you call the *EnsureDispatcherQueue*, *CreateDesktopWindowTarget*, and *CreateCompositionRoot* methods. You create these methods in the next steps.

- In CompositionHost.h, declare a public method named *Initialize* that takes an HWND as an argument.

C++/WinRT

```
void Initialize(HWND hwnd);
```

- In CompositionHost.cpp, add the definition of the *Initialize* method.

C++/WinRT

```
void CompositionHost::Initialize(HWND hwnd)
{
    EnsureDispatcherQueue();
    if (m_dispatcherQueueController) m_compositor = Compositor();

    CreateDesktopWindowTarget(hwnd);
    CreateCompositionRoot();
}
```

6. Create a dispatcher queue on the thread that will be using Windows Composition.

   A Compositor must be created on a thread that has a dispatcher queue, so this method is called first during initialization.

- In CompositionHost.h, declare a private method named *EnsureDispatcherQueue*.

C++/WinRT

```
void EnsureDispatcherQueue();
```

- In CompositionHost.cpp, add the definition of the *EnsureDispatcherQueue* method.

C++/WinRT

```
void CompositionHost::EnsureDispatcherQueue()
{
    namespace abi = ABI::Windows::System;

    if (m_dispatcherQueueController == nullptr)
    {
        DispatcherQueueOptions options
        {
            sizeof(DispatcherQueueOptions), /* dwSize */
            DQTYPE_THREAD_CURRENT,          /* threadType */
            DQTAT_COM_ASTA                  /* apartmentType */
        };

        Windows::System::DispatcherQueueController controller{ nullptr
};
        check_hresult(CreateDispatcherQueueController(options,
reinterpret_cast<abi::IDispatcherQueueController**>
(put_abi(controller))));
        m_dispatcherQueueController = controller;
    }
}
```

7. Register your app's window as a composition target.

- In CompositionHost.h, declare a private method named *CreateDesktopWindowTarget* that takes an HWND as an argument.

C++/WinRT

```
void CreateDesktopWindowTarget(HWND window);
```

- In CompositionHost.cpp, add the definition of the *CreateDesktopWindowTarget* method.

C++/WinRT

```
void CompositionHost::CreateDesktopWindowTarget(HWND window)
{
    namespace abi = ABI::Windows::UI::Composition::Desktop;

    auto interop = m_compositor.as<abi::ICompositorDesktopInterop>();
    DesktopWindowTarget target{ nullptr };
    check_hresult(interop->CreateDesktopWindowTarget(window, false,
reinterpret_cast<abi::IDesktopWindowTarget**>(put_abi(target))));
```

```
    m_target = target;
}
```

8. Create a root visual container to hold visual objects.

    - In CompositionHost.h, declare a private method named *CreateCompositionRoot*.

C++/WinRT

```
void CreateCompositionRoot();
```

    - In CompositionHost.cpp, add the definition of the *CreateCompositionRoot* method.

C++/WinRT

```
void CompositionHost::CreateCompositionRoot()
{
    auto root = m_compositor.CreateContainerVisual();
    root.RelativeSizeAdjustment({ 1.0f, 1.0f });
    root.Offset({ 124, 12, 0 });
    m_target.Root(root);
}
```

Build the project now to make sure there are no errors.

These methods set up the components needed for interop between the UWP visual layer and Win32 APIs. Now you can add content to your app.

Add composition elements

With the infrastructure in place, you can now generate the Composition content you want to show.

For this example, you add code that creates a randomly-colored square SpriteVisual with an animation that causes it to drop after a short delay.

1. Add a composition element.

    - In CompositionHost.h, declare a public method named *AddElement* that takes 3 **float** values as arguments.

C++/WinRT

```
void AddElement(float size, float x, float y);
```

- In CompositionHost.cpp, add the definition of the *AddElement* method.

C++/WinRT

```
void CompositionHost::AddElement(float size, float x, float y)
{
    if (m_target.Root())
    {
        auto visuals = m_target.Root().as<ContainerVisual>
().Children();
        auto visual = m_compositor.CreateSpriteVisual();

        auto element = m_compositor.CreateSpriteVisual();
        uint8_t r = (double)(double)(rand() % 255);;
        uint8_t g = (double)(double)(rand() % 255);;
        uint8_t b = (double)(double)(rand() % 255);;

        element.Brush(m_compositor.CreateColorBrush({ 255, r, g, b }));
        element.Size({ size, size });
        element.Offset({ x, y, 0.0f, });

        auto animation = m_compositor.CreateVector3KeyFrameAnimation();
        auto bottom = (float)600 - element.Size().y;
        animation.InsertKeyFrame(1, { element.Offset().x, bottom, 0 });

        using timeSpan = std::chrono::duration<int, std::ratio<1, 1>>;

        std::chrono::seconds duration(2);
        std::chrono::seconds delay(3);

        animation.Duration(timeSpan(duration));
        animation.DelayTime(timeSpan(delay));
        element.StartAnimation(L"Offset", animation);
        visuals.InsertAtTop(element);

        visuals.InsertAtTop(visual);
    }
}
```

Create and show the window

Now, you can add a button and the UWP composition content to your Win32 UI.

1. In HelloComposition.cpp, at the top of the file, include *CompositionHost.h*, define BTN_ADD, and get an instance of CompositionHost.

C++/WinRT

```
#include "CompositionHost.h"

// #define MAX_LOADSTRING 100 // This is already in the file.
#define BTN_ADD 1000

CompositionHost* compHost = CompositionHost::GetInstance();
```

2. In the `InitInstance` method, change the size of the window that's created. (In this line, change `CW_USEDEFAULT, 0` to `900, 672`.)

C++/WinRT

```
HWND hWnd = CreateWindowW(szWindowClass, szTitle, WS_OVERLAPPEDWINDOW,
    CW_USEDEFAULT, 0, 900, 672, nullptr, nullptr, hInstance, nullptr);
```

3. In the WndProc function, add `case WM_CREATE` to the *message* switch block. In this case, you initialize the CompositionHost and create the button.

C++/WinRT

```
case WM_CREATE:
{
    compHost->Initialize(hWnd);
    srand(time(nullptr));

    CreateWindow(TEXT("button"), TEXT("Add element"),
        WS_VISIBLE | WS_CHILD | BS_PUSHBUTTON,
        12, 12, 100, 50,
        hWnd, (HMENU)BTN_ADD, nullptr, nullptr);
}
break;
```

4. Also in the WndProc function, handle the button click to add a composition element to the UI.

   Add `case BTN_ADD` to the *wmId* switch block inside the WM_COMMAND block.

C++/WinRT

```
case BTN_ADD: // addButton click
{
    double size = (double)(rand() % 150 + 50);
    double x = (double)(rand() % 600);
    double y = (double)(rand() % 200);
    compHost->AddElement(size, x, y);
```

```
        break;
    }
```

You can now build and run your app. If you need to, check the complete code at the end of the tutorial to make sure all the code is in the right places.

When you run the app and click the button, you should see animated squares added to the UI.

Complete code

Here's the complete code for the CompositionHost class and the InitInstance method.

CompositionHost.h

C++/WinRT

```
#pragma once
#include <winrt/Windows.UI.Composition.Desktop.h>
#include <windows.ui.composition.interop.h>
#include <DispatcherQueue.h>

class CompositionHost
{
public:
    ~CompositionHost();
    static CompositionHost* GetInstance();

    void Initialize(HWND hwnd);
    void AddElement(float size, float x, float y);

private:
    CompositionHost();

    void CreateDesktopWindowTarget(HWND window);
    void EnsureDispatcherQueue();
    void CreateCompositionRoot();
```

```
    winrt::Windows::UI::Composition::Compositor m_compositor{ nullptr };
    winrt::Windows::UI::Composition::Desktop::DesktopWindowTarget m_target{
nullptr };
    winrt::Windows::System::DispatcherQueueController
m_dispatcherQueueController{ nullptr };
};
```

CompositionHost.cpp

C++/WinRT

```
#include "pch.h"
#include "CompositionHost.h"

using namespace winrt;
using namespace Windows::System;
using namespace Windows::UI;
using namespace Windows::UI::Composition;
using namespace Windows::UI::Composition::Desktop;
using namespace Windows::Foundation::Numerics;

CompositionHost::CompositionHost()
{
}

CompositionHost* CompositionHost::GetInstance()
{
    static CompositionHost instance;
    return &instance;
}

CompositionHost::~CompositionHost()
{
}

void CompositionHost::Initialize(HWND hwnd)
{
    EnsureDispatcherQueue();
    if (m_dispatcherQueueController) m_compositor = Compositor();

    if (m_compositor)
    {
        CreateDesktopWindowTarget(hwnd);
        CreateCompositionRoot();
    }
}

void CompositionHost::EnsureDispatcherQueue()
{
    namespace abi = ABI::Windows::System;

    if (m_dispatcherQueueController == nullptr)
```

```
    {
        DispatcherQueueOptions options
        {
            sizeof(DispatcherQueueOptions), /* dwSize */
            DQTYPE_THREAD_CURRENT,          /* threadType */
            DQTAT_COM_ASTA                  /* apartmentType */
        };

        Windows::System::DispatcherQueueController controller{ nullptr };
        check_hresult(CreateDispatcherQueueController(options,
reinterpret_cast<abi::IDispatcherQueueController**>(put_abi(controller))));
        m_dispatcherQueueController = controller;
    }
}

void CompositionHost::CreateDesktopWindowTarget(HWND window)
{
    namespace abi = ABI::Windows::UI::Composition::Desktop;

    auto interop = m_compositor.as<abi::ICompositorDesktopInterop>();
    DesktopWindowTarget target{ nullptr };
    check_hresult(interop->CreateDesktopWindowTarget(window, false,
reinterpret_cast<abi::IDesktopWindowTarget**>(put_abi(target))));
    m_target = target;
}

void CompositionHost::CreateCompositionRoot()
{
    auto root = m_compositor.CreateContainerVisual();
    root.RelativeSizeAdjustment({ 1.0f, 1.0f });
    root.Offset({ 124, 12, 0 });
    m_target.Root(root);
}

void CompositionHost::AddElement(float size, float x, float y)
{
    if (m_target.Root())
    {
        auto visuals = m_target.Root().as<ContainerVisual>().Children();
        auto visual = m_compositor.CreateSpriteVisual();

        auto element = m_compositor.CreateSpriteVisual();
        uint8_t r = (double)(double)(rand() % 255);;
        uint8_t g = (double)(double)(rand() % 255);;
        uint8_t b = (double)(double)(rand() % 255);;

        element.Brush(m_compositor.CreateColorBrush({ 255, r, g, b }));
        element.Size({ size, size });
        element.Offset({ x, y, 0.0f, });

        auto animation = m_compositor.CreateVector3KeyFrameAnimation();
        auto bottom = (float)600 - element.Size().y;
        animation.InsertKeyFrame(1, { element.Offset().x, bottom, 0 });

        using timeSpan = std::chrono::duration<int, std::ratio<1, 1>>;
```

```
        std::chrono::seconds duration(2);
        std::chrono::seconds delay(3);

        animation.Duration(timeSpan(duration));
        animation.DelayTime(timeSpan(delay));
        element.StartAnimation(L"Offset", animation);
        visuals.InsertAtTop(element);

        visuals.InsertAtTop(visual);
    }
}
```

HelloComposition.cpp (Partial)

C++/WinRT

```
#include "pch.h"
#include "HelloComposition.h"
#include "CompositionHost.h"

#define MAX_LOADSTRING 100
#define BTN_ADD 1000

CompositionHost* compHost = CompositionHost::GetInstance();

// Global Variables:

// ...
// ... code not shown ...
// ...

BOOL InitInstance(HINSTANCE hInstance, int nCmdShow)
{
   hInst = hInstance; // Store instance handle in our global variable

   HWND hWnd = CreateWindowW(szWindowClass, szTitle, WS_OVERLAPPEDWINDOW,
      CW_USEDEFAULT, 0, 900, 672, nullptr, nullptr, hInstance, nullptr);

// ...
// ... code not shown ...
// ...
}

// ...

LRESULT CALLBACK WndProc(HWND hWnd, UINT message, WPARAM wParam, LPARAM
lParam)
{
    switch (message)
    {
// Add this...
```

```
    case WM_CREATE:
    {
        compHost->Initialize(hWnd);
        srand(time(nullptr));

        CreateWindow(TEXT("button"), TEXT("Add element"),
            WS_VISIBLE | WS_CHILD | BS_PUSHBUTTON,
            12, 12, 100, 50,
            hWnd, (HMENU)BTN_ADD, nullptr, nullptr);
    }
    break;
// ...
    case WM_COMMAND:

C#/WinRT

Article • 03/16/2023

C#/WinRT is a NuGet-packaged toolkit that provides Windows Runtime (WinRT) projection support for the C# language. A projection assembly is an interop assembly, which enables programming WinRT APIs in a natural and familiar way for the target language. The C#/WinRT projection hides the details of interop between C# and WinRT interfaces, and provides mappings of many WinRT types to appropriate .NET equivalents, such as strings, URIs, common value types, and generic collections.

C#/WinRT currently provides support for consuming WinRT APIs through the use of Target Framework Monikers (TFMs) in .NET. Setting the TFM with a specific Windows SDK version adds references to the Windows SDK projection and runtime assemblies generated by C#/WinRT.

The C#/WinRT NuGet package enables you to create and reference your own WinRT interop assemblies for .NET consumers. The latest C#/WinRT version also includes a preview of authoring WinRT types in C#.

For additional information, see the C#/WinRT GitHub repo.

Motivation for C#/WinRT

.NET (previously known as .NET Core) is an open-source, cross-platform runtime that can be used to build device, cloud, and IoT applications.

Previous versions of .NET Framework and .NET Core had built-in knowledge of WinRT—a Windows-specific technology. To support the portability and efficiency goals of .NET 6+, we lifted the WinRT projection support out of the .NET compiler and runtime and moved it into the C#/WinRT toolkit (see Built-in support for WinRT is removed from .NET). The goal of C#/WinRT is to provide parity with the built-in WinRT support provided by earlier versions of the C# compiler and .NET runtime. For details, see .NET mappings of Windows Runtime types.

C#/WinRT also supports components in the Windows App SDK, including WinUI 3. The Windows App SDK lifts native Microsoft UI controls and other native components out of the operating system. This enables app developers to use the latest controls and components on Windows 10, version 1809, and later releases.

Finally, C#/WinRT is a general toolkit and is intended to support other scenarios where built-in support for WinRT is not available in the C# compiler or .NET runtime.

What's new

The latest C#/WinRT releases can be found on our release notes page in the Github repo.

Usage

The C#/WinRT NuGet package can be used to both generate C# projections (also called interop assemblies) from WinRT components and in Authoring C#/WinRT components. For more details regarding the usage scenarios for C#/WinRT, refer to the usage guide on our repo.

Generate and distribute an interop assembly

WinRT APIs are defined in Windows Metadata (WinMD) files. The C#/WinRT NuGet package (Microsoft.Windows.CsWinRT) includes the C#/WinRT compiler, **cswinrt.exe**, which you can use to process WinMD files and generate .NET C# code. C#/WinRT compiles these source files into an interop assembly, similar to how C++/WinRT generates headers for the C++ language projection. You can then distribute the C#/WinRT interop assembly along with the implementation assembly for .NET applications to reference, typically as a NuGet package.

For more details on how to generate and distribute an interop assembly, see Generate a C# projection from a C++/WinRT component, distribute as a NuGet for .NET apps.

Reference an interop assembly

Typically, C#/WinRT interop assemblies are referenced by application projects. But they may also be referenced in turn by intermediate interop assemblies. For example, the WinUI interop assembly would reference the Windows SDK interop assembly.

If you distribute a third-party WinRT component without an official interop assembly, an application project may follow the procedure for generating an interop assembly to generate its own private projection sources. We don't recommend this approach, because it can produce conflicting projections of the same type within a process. NuGet packaging, following the Semantic Versioning scheme, is designed to prevent this. An official third-party interop assembly is preferred.

Embedded support for WinRT types (Preview)

Starting with C#/WinRT version 1.4.1, support is included for embedding Windows SDK projection and runtime sources for both .NET and .NET Standard 2.0 into your library or app's output. This is useful in cases where usage of Windows SDK types is self-contained. Embedded support removes dependencies on WinRT.Runtime.dll and Microsoft.Windows.SDK.NET.dll which reduces the library or app output size. It also allows library developers to provide downlevel support and removes the need for multi-targeting.

For more details, see the C#/WinRT embedded documentation on our repo.

WinRT type activation

C#/WinRT supports activation of WinRT types hosted by the operating system, as well as third-party components such as Win2D. Support for third-party component activation in a desktop application is enabled with registration free WinRT activation (see Enhancing Non-packaged Desktop Apps using Windows Runtime Components), available in Windows 10, version 1903 and later. Native C++ components should set the **Windows Desktop Compatible** property to *True* either via the project properties or the `.vcxproj` file, in order to reference and forward the **Microsoft.VCLibs.Desktop** binaries to consuming apps. Otherwise, the VCRT Forwarders package will be required by consuming apps if the component targets UWP apps only.

C#/WinRT also provides an activation fallback path if Windows fails to activate the type as described above. In this case, C#/WinRT attempts to locate a native implementation DLL based on the fully qualified type name, progressively removing elements. For example, the fallback logic would attempt to activate the Contoso.Controls.Widget type from the following modules, in sequence:

1. Contoso.Controls.Widget.dll
2. Contoso.Controls.dll
3. Contoso.dll

C#/WinRT uses the LoadLibrary alternate search order to locate an implementation DLL. An app relying on this fallback behavior should package the implementation DLL alongside the app module.

Common errors and troubleshooting

- Error: "Windows Metadata not provided or detected."

  You can specify Windows Metadata by using the `<CsWinRTWindowsMetadata>` project property, for example:

```xml
<CsWinRTWindowsMetadata>10.0.19041.0</CsWinRTWindowsMetadata>
```

In C#/WinRT version 1.2.1 and later, this property defaults to `TargetPlatformVersion`, which is derived from the Windows SDK version specified in the `TargetFramework` property.

- Error CS0246: The type or namespace name 'Windows' could not be found (are you missing a using directive or an assembly reference?)

  To address this error, edit your `<TargetFramework>` property to target a specific Windows version, for example:

  ```xml
  <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
  ```

  Refer to the docs on Calling Windows Runtime APIs for more details on specifying the `<TargetFramework>` property.

- **System.InvalidCastException** when casting to an interface that has the `ComImport` attribute

  When casting an object to an interface that has the `ComImport` attribute, you'll need to use the `.As<>` operator instead of using an explicit cast expression. For example:

  ```C#
  someObject.As<SomeComImportInterface>
  ```

  For more details, see the COM interop guide.

- System.Runtime.InteropServices.COMException: Class not registered (0x80040154 (REGDB_E_CLASSNOTREG))
  - If you see this exception when consuming a C#/WinRT projection from a C++/WinRT component, make sure the component has set the **Windows Desktop Compatible** property to *True* either via the project properties or via the `.vcxproj` file.

.NET SDK versioning errors

You may encounter the following errors or warnings in a project that is built with an earlier .NET SDK version than any of its dependencies.

Expand table

Error or warning message	Reason
Warning MSB3277: Found conflicts between different versions of WinRT.Runtime or Microsoft.Windows.SDK.NET that could not be resolved.	This build warning occurs when referencing a library that exposes Windows SDK types on its API surface.
Error CS1705: Assembly 'AssemblyName1' uses 'TypeName' which has a higher version than referenced assembly 'AssemblyName2'	This build compiler error occurs when referencing and consuming exposed Windows SDK types in a library.
System.IO.FileLoadException	This runtime error may occur when calling certain APIs in a library that does not expose Windows SDK types.

To fix these errors, update your .NET SDK to the latest version. Doing so will ensure that the runtime and Windows SDK assembly versions used by your application are compatible with all dependencies. These errors may occur with early servicing/feature updates to the .NET SDK, because runtime fixes may require updates to our assembly versions.

Known issues

Known issues and breaking changes are noted in the C#/WinRT GitHub repo.

If you encounter any functional issues with the C#/WinRT NuGet package, the cswinrt.exe compiler, or the generated projection sources, submit issues to us via the C#/WinRT issues page.

.NET mappings of WinRT types in C#/WinRT

Article • 10/24/2022

This article lists the mappings that C#/WinRT makes between Windows Runtime (WinRT) types and .NET types in desktop apps that target .NET 6 (or later). In these apps, Visual Studio IntelliSense shows the .NET type instead of the Windows Runtime type. For example, if a Windows Runtime method takes a parameter of type **IVector<string>**, then IntelliSense shows a parameter of type **IList<string>**. Similarly, in a WinRT component authored using C#/WinRT, you use the .NET type in member signatures. When you use C#/WinRT to generate a Windows Runtime component, the .NET type is translated into the corresponding WinRT type.

The C#/WinRT custom type mappings are categorized by types in the Windows SDK or in WinUI 3 (WinUI 3 is part of the Windows App SDK). The WinRT types for Windows SDK mappings live under the **Windows.*** namespaces, and the WinRT types for WinUI 3 mappings live under the **Microsoft.UI.Xaml.*** namespaces. There are two reasons for custom type mappings that C#/WinRT makes for WinRT types:

- **WinRT types that map to .NET types with a different name and/or namespace.** These custom mappings are for mapping WinRT types to existing .NET equivalent types. There are also cases where the mapping is to a different type (e.g., a value type maps to a class type).
- **WinRT types that map to .NET types with the same name and namespace.** These custom mappings are generally for performance or enhancement reasons, and are implemented directly in C#. Most of the types that have the same namespace name and type name in WinRT and .NET are structures (or types associated with structures, such as enumerations). In WinRT, structures have no members other than fields, and require helper types, which .NET hides. The .NET versions of these structures have properties and methods that provide the functionality of the hidden helper types (for example, **Windows.UI.Color**).

> ⓘ **Note**
>
> For a list of mappings between WinRT and .NET types in the context of UWP apps, see **.NET mappings of WinRT types in UWP**.

Mappings for WinRT types in the Windows SDK

Types with a different name and/or namespace

WinRT type/namespace	.NET type/namespace
DateTime (Windows.Foundation)	DateTimeOffset (System)
EventHandler<T> (Windows.Foundation)	EventHandler<T> (System)

Agile objects in C#/WinRT

Article • 01/15/2022

Most Windows Runtime classes are *agile*, meaning they can be accessed from any threads across different apartments. C#/WinRT types that you author are agile by default, and it is not possible to opt out of this behavior for those types.

However, projected C#/WinRT types (which includes Windows Runtime types that are provided by the Windows SDK and the WinUI library) may or may not be agile. For example, many types that represent UI objects are not agile. When you consume non-agile types, you need to take into consideration their threading model and marshaling behavior. C#/WinRT provides support for agile references if you need to marshal a non-agile object across apartments in a safe way.

> **Note**
>
> The Windows Runtime is based on COM. In COM terms, an agile class is registered with `ThreadingModel` = *Both*. For more info about COM threading models, and apartments, see **Understanding and Using COM Threading Models**.

Check for agile support

To check whether a Windows Runtime object is agile, use the following code to determine whether the object supports the IAgileObject interface.

C#

```
var queryAgileObject = testObject.As<IAgileObject>();

if (queryAgileObject != null) {
    // testObject is agile.
}
```

Create an agile reference

To create an agile reference for a non-agile object, you can use the `AsAgile` extension method. `AsAgile` is a generic extension method that can be applied to any projected C#/WinRT type. If the type is not a projected type, an exception is thrown. Here is an example using a PopupMenu object, which is a non-agile type from the Windows SDK.

C#

```
var nonAgileObj = new Windows.UI.Popups.PopupMenu();
AgileReference<Windows.UI.Popups.PopupMenu> agileReference =
nonAgileObj.AsAgile();
```

You can now pass `agileReference` to a thread in a different apartment, and use it there.

C#

```
await Task.Run(() => {
        Windows.UI.Popups.PopupMenu nonAgileObjAgain = agileReference.Get()
    });
```

Generate a C# projection from a C++/WinRT component, distribute as a NuGet for .NET apps

Article • 03/23/2023

In this topic, we walk through using C#/WinRT to generate a C# .NET projection (or interop) assembly from a C++/WinRT Windows Runtime component, and distribute it as a NuGet package for .NET applications.

In .NET 6 and later, consumption of Windows metadata (WinMD) files is no longer supported (see Built-in support for WinRT is removed from .NET). Instead, the C#/WinRT tool can be used to generate a projection assembly for any WinMD file, which then enables consumption of WinRT components from .NET applications. A projection assembly is also known as an interop assembly. This walkthrough shows you how to do the following:

- Use the C#/WinRT package to generate a C# projection from a C++/WinRT component.
- Distribute the component, along with the projection assembly, as a NuGet package.
- Consume the NuGet package from a .NET console application.

Prerequisites

This walkthrough and the corresponding sample require the following tools and components:

- Visual Studio 2022 (or Visual Studio 2019) with the Universal Windows Platform development workload installed. In **Installation Details** > **Universal Windows Platform development**, check the **C++ (v14x) Universal Windows Platform tools** option.
- .NET 6.0 SDK or later.

Visual Studio 2019 only. The C++/WinRT VSIX extension, which gives you C++/WinRT project templates in Visual Studio. The project templates are built in to Visual Studio 2022.

We'll be using Visual Studio 2022 and .NET 6 in this walkthrough.

> **ⓘ Important**
>
> Also, you'll need to download or clone the sample code for this topic from the C#/WinRT projection sample on GitHub. Visit CsWinRT, and click the green **Code** button to get the `git clone` url. Be sure to read the README.md file for the sample.

Create a simple C++/WinRT Windows Runtime component

To follow this walkthrough, you must first have a C++/WinRT Windows Runtime component (WRC) from which to generate the C# projection assembly.

This walkthrough uses the **SimpleMathComponent** WRC from the C#/WinRT projection sample on GitHub, which you already downloaded or cloned. **SimpleMathComponent** was created from the **Windows Runtime Component (C++/WinRT)** Visual Studio project template (which comes with Visual Studio 2022, or with the C++/WinRT VSIX extension).

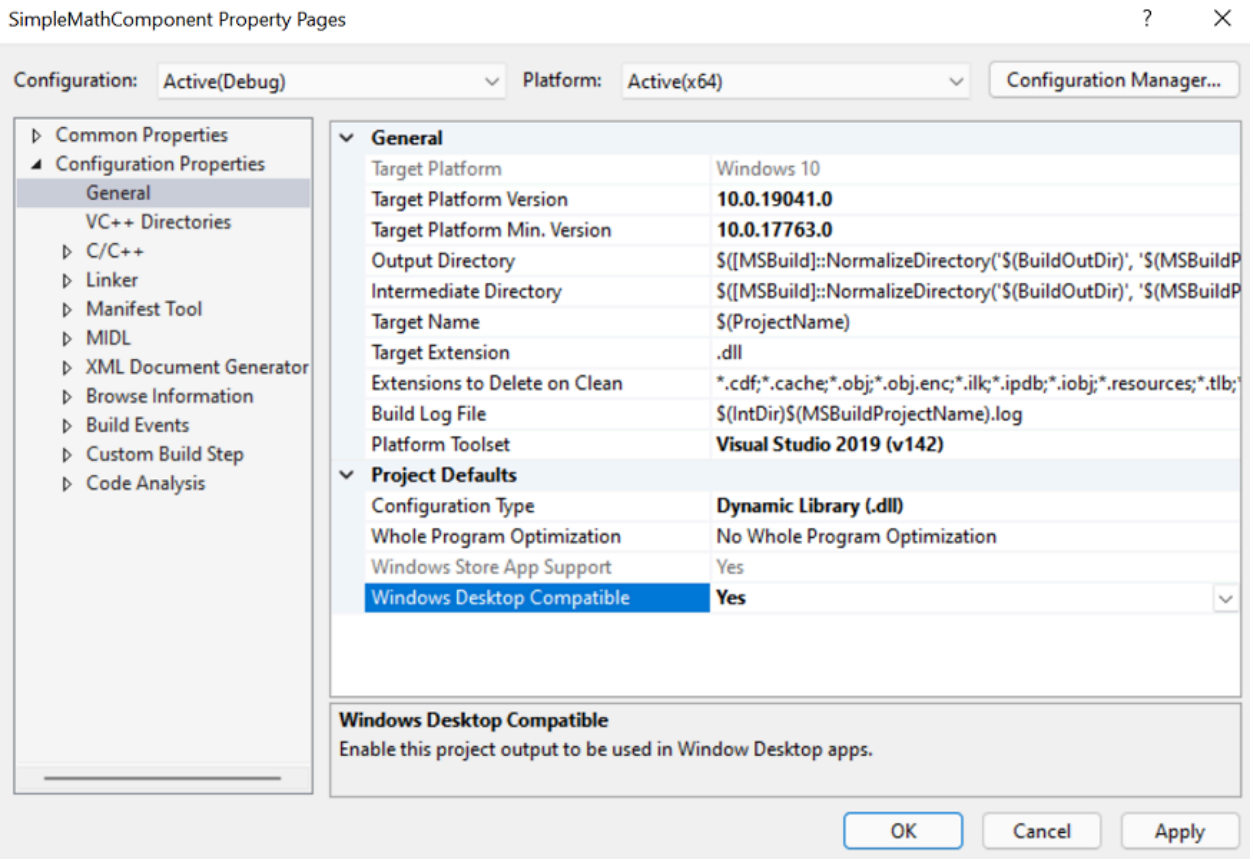
To open the **SimpleMathComponent** project in Visual Studio, open the `\CsWinRT\src\Samples\NetProjectionSample\CppWinRTComponentProjectionSample.sln` file, which you'll find in your download or clone of the repo.

The code in this project provides the functionality for the basic math operations shown in the header file below.

C++

```
// SimpleMath.h
...
namespace winrt::SimpleMathComponent::implementation
{
    struct SimpleMath: SimpleMathT<SimpleMath>
    {
        SimpleMath() = default;
        double add(double firstNumber, double secondNumber);
        double subtract(double firstNumber, double secondNumber);
        double multiply(double firstNumber, double secondNumber);
        double divide(double firstNumber, double secondNumber);
    };
}
```

You can confirm that the **Windows Desktop Compatible** property is set to *Yes* for the **SimpleMathComponent** C++/WinRT Windows Runtime component project. To do that, in the project properties for **SimpleMathComponent**, under **Configuration Properties** > **General** > **Project Defaults**, set the property **Windows Desktop Compatible** to *Yes*. That ensures that the correct runtime binaries are loaded for consuming .NET desktop apps.



For more detailed steps about creating a C++/WinRT component and generating a WinMD file, see Windows Runtime components with C++/WinRT.

> **Note**
>
> If you're implementing IInspectable::GetRuntimeClassName in your component, then it **must** return a valid WinRT class name. Because C#/WinRT uses the class name string for interop, an incorrect runtime class name will raise an **InvalidCastException**.

Add a projection project to the component solution

First, with the **CppWinRTComponentProjectionSample** solution still open in Visual Studio, remove the **SimpleMathProjection** project from that solution. Then delete from

your file system the **SimpleMathProjection** folder (or rename it if you prefer). Those steps are necessary so that you can follow this walkthrough step by step.

1. Add a new C# library project to your solution.
   a. In **Solution Explorer**, right-click your solution node and click **Add** > **New Project**.
   b. In the **Add a new project** dialog box, type **Class Library** in the search box. Choose **C#** from the language list, and then choose **Windows** from the platform list. Choose the C# project template that's called simply **Class Library** (with no prefixes nor suffixes), and click **Next**.
   c. Name the new project *SimpleMathProjection*. The location should already be set to the same `\CsWinRT\src\Samples\NetProjectionSample` folder that the **SimpleMathComponent** folder is in; but confirm that. Then click **Next**.
   d. On the **Additional information** page, select **.NET 6.0 (Long-term support)**, and then choose **Create**.

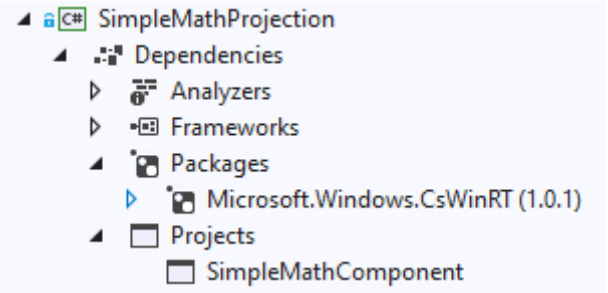
2. Delete the stub **Class1.cs** file from the project.

3. Use the steps below to install the C#/WinRT NuGet package.
   a. In **Solution Explorer**, right-click your **SimpleMathProjection** project and select **Manage NuGet Packages**.
   b. In the **Browse** tab, type or paste **Microsoft.Windows.CsWinRT** into the search box, in search results select the item with the latest version, and then click **Install** to install the package into the **SimpleMathProjection** project.

4. Add to **SimpleMathProjection** a project reference to the **SimpleMathComponent** project. In **Solution Explorer**, right-click the **Dependencies** node under the **SimpleMathProjection** project node, select **Add Project Reference**, and select the **SimpleMathComponent** project > **OK**.

Don't try to build the project yet. We'll be doing that in a later step.

So far, your **Solution Explorer** should look similar to this (your version numbers will be different).



Build projects out of source

For the **CppWinRTComponentProjectionSample** solution in the C#/WinRT projection sample (which you downloaded or cloned from GitHub, and now have open), the build output location is configured with the **Directory.Build.props** file to build *out of source*. That means that files from the build output are generated outside of the source folder. We recommend that you build out of source when you use the C#/WinRT tool. That prevents the C# compiler from inadvertently picking up all **.cs* files under the project root directory, which can cause duplicate type errors (for example when compiling for multiple configurations and/or platforms).

Even though this is already configured for the **CppWinRTComponentProjectionSample** solution, follow the steps below to get practice in doing the configuration for yourself.

To configure your solution to build out of source:

1. With the **CppWinRTComponentProjectionSample** solution still open, right-click on the solution node, and select **Add** > **New Item**. Select the **XML File** item, and name it **Directory.Build.props** (without a `.xml` extension). Click **Yes** to overwrite the existing file.

2. Replace the contents of **Directory.Build.props** with the configuration below.

   XML

   ```
   <Project>
     <PropertyGroup>
       <BuildOutDir>$([MSBuild]::NormalizeDirectory('$(SolutionDir)',
   '_build', '$(Platform)', '$(Configuration)'))</BuildOutDir>
       <OutDir>$([MSBuild]::NormalizeDirectory('$(BuildOutDir)',
   '$(MSBuildProjectName)', 'bin'))</OutDir>
       <IntDir>$([MSBuild]::NormalizeDirectory('$(BuildOutDir)',
   '$(MSBuildProjectName)', 'obj'))</IntDir>
     </PropertyGroup>
   </Project>
   ```

3. Save and close the **Directory.Build.props** file.

Edit the project file to execute C#/WinRT

Before you can invoke the `cswinrt.exe` tool to generate the projection assembly, you must first edit the project file to specify a few project properties.

1. In **Solution Explorer**, double-click the **SimpleMathProjection** node to open the project file in the editor.

2. Update the `TargetFramework` element to target a specific Windows SDK version. This adds assembly dependencies that are necessary for the interop and projection support. This sample targets the Windows SDK version **net6.0-windows10.0.19041.0** (also known as Windows 10, version 2004). Set the `Platform` element to **AnyCPU** so that the resulting projection assembly can be referenced from any app architecture. To allow referencing applications to support earlier Windows SDK versions, you can also set the `TargetPlatformMinimumVersion` property.

   XML

   ```
   <PropertyGroup>
     <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
     <!-- Set Platform to AnyCPU to allow consumption of the projection
   assembly from any architecture. -->
     <Platform>AnyCPU</Platform>
   </PropertyGroup>
   ```

   > **Note**
   >
   > For this walkthrough and the related sample code, the solution is built for **x64** and **Release**. Note that the **SimpleMathProjection** project is configured to build for AnyCPU for all solution architecture configurations.

3. Add a second `PropertyGroup` element (immediately after the first) that sets several C#/WinRT properties.

   XML

   ```
   <PropertyGroup>
     <CsWinRTIncludes>SimpleMathComponent</CsWinRTIncludes>
     <CsWinRTGeneratedFilesDir>$(OutDir)</CsWinRTGeneratedFilesDir>
   </PropertyGroup>
   ```

   Here are some details about the settings in this example:

   - The `CsWinRTIncludes` property specifies which namespaces to project.
   - The `CsWinRTGeneratedFilesDir` property sets the output directory in which the projection source files are generated. This property is set to `OutDir`, defined in **Directory.Build.props** from the section above.

4. Save and close the **SimpleMathProjection.csproj** file, and click to **Reload projects** if necessary.

Create a NuGet package with the projection

To distribute the projection assembly for .NET application developers, you can automatically create a NuGet package when building the solution by adding some additional project properties. For .NET targets, the NuGet package needs to include the projection assembly and the implementation assembly from the component.

1. Use the steps below to add a NuGet spec (`.nuspec`) file to the **SimpleMathProjection** project.
   a. In **Solution Explorer**, right-click the **SimpleMathProjection** node, choose **Add** > **New Folder**, and name the folder **nuget**.
   b. Right-click the **nuget** folder, choose **Add** > **New Item**, choose **XML file**, and name it **SimpleMathProjection.nuspec**.

2. In **Solution Explorer**, double-click the **SimpleMathProjection** node to open the project file in the editor. Add the following property group to the now-open **SimpleMathProjection.csproj** (immediately after the two existing `PropertyGroup` elements) to automatically generate the package. These properties specify the `NuspecFile` and the directory to generate the NuGet package.

   XML

   ```
   <PropertyGroup>
     <GeneratedNugetDir>.\nuget\</GeneratedNugetDir>

   <NuspecFile>$(GeneratedNugetDir)SimpleMathProjection.nuspec</NuspecFile
   >
     <OutputPath>$(GeneratedNugetDir)</OutputPath>
     <GeneratePackageOnBuild>true</GeneratePackageOnBuild>
   </PropertyGroup>
   ```

   > **Note**
   >
   > If you prefer generating a package separately, then you can also choose to run the `nuget.exe` tool from the command line. For more information about creating a NuGet package, see Create a package using the nuget.exe CLI.

3. Open the **SimpleMathProjection.nuspec** file to edit the package creation properties, and paste the following code. The snippet below is an example NuGet spec for distributing **SimpleMathComponent** to multiple target frameworks. Note that projection assembly, **SimpleMathProjection.dll**, is specified instead of **SimpleMathComponent.winmd** for the target `lib\net6.0-`

`windows10.0.19041.0\SimpleMathProjection.dll`. This behavior is new in .NET 6 and later, and is enabled by C#/WinRT. The implementation assembly, `SimpleMathComponent.dll`, must also be distributed, and will be loaded at runtime.

XML

```
<?xml version="1.0" encoding="utf-8"?>
<package
xmlns="http://schemas.microsoft.com/packaging/2012/06/nuspec.xsd">
  <metadata>
    <id>SimpleMathComponent</id>
    <version>0.1.0-prerelease</version>
    <authors>Contoso Math Inc.</authors>
    <description>A simple component with basic math
operations</description>
    <dependencies>
      <group targetFramework="net6.0-windows10.0.19041.0" />
      <group targetFramework=".NETCoreApp3.0" />
      <group targetFramework="UAP10.0" />
      <group targetFramework=".NETFramework4.6" />
    </dependencies>
  </metadata>
  <files>
    <!--Support .NET 6, .NET Core 3, UAP, .NET Framework 4.6, C++ -->
    <!--Architecture-neutral assemblies-->
    <file
src="..\..\_build\AnyCPU\Release\SimpleMathProjection\bin\SimpleMathPro
jection.dll" target="lib\net6.0-
windows10.0.19041.0\SimpleMathProjection.dll" />
    <file
src="..\..\_build\x64\Release\SimpleMathComponent\bin\SimpleMathCompone
nt\SimpleMathComponent.winmd"
target="lib\netcoreapp3.0\SimpleMathComponent.winmd" />
    <file
src="..\..\_build\x64\Release\SimpleMathComponent\bin\SimpleMathCompone
nt\SimpleMathComponent.winmd"
target="lib\uap10.0\SimpleMathComponent.winmd" />
    <file
src="..\..\_build\x64\Release\SimpleMathComponent\bin\SimpleMathCompone
nt\SimpleMathComponent.winmd"
target="lib\net46\SimpleMathComponent.winmd" />
    <!--Architecture-specific implementation DLLs should be copied into
RID-relative folders-->
    <file
src="..\..\_build\x64\Release\SimpleMathComponent\bin\SimpleMathCompone
nt\SimpleMathComponent.dll" target="runtimes\win10-
x64\native\SimpleMathComponent.dll" />
    <!--To support x86 and Arm64, build SimpleMathComponent for those
other architectures and uncomment the entries below.-->
    <!--<file
src="..\..\_build\Win32\Release\SimpleMathComponent\bin\SimpleMathCompo
nent\SimpleMathComponent.dll" target="runtimes\win10-
x86\native\SimpleMathComponent.dll" />-->
```

```
    <!--<file
src="..\..\_build\arm64\Release\SimpleMathComponent\bin\SimpleMathCompo
nent\SimpleMathComponent.dll" target="runtimes\win10-
arm64\native\SimpleMathComponent.dll" />-->
  </files>
</package>
```

> **Note**
>
> **SimpleMathComponent.dll**, the implementation assembly for the component, is architecture-specific. If you're supporting other platforms (for example, x86 or Arm64), then you must first build **SimpleMathComponent** for the desired platforms, and add these assembly files to the appropriate RID-relative folder. The projection assembly **SimpleMathProjection.dll** and the component **SimpleMathComponent.winmd** are both architecture-neutral.

4. Save and close the files you just edited.

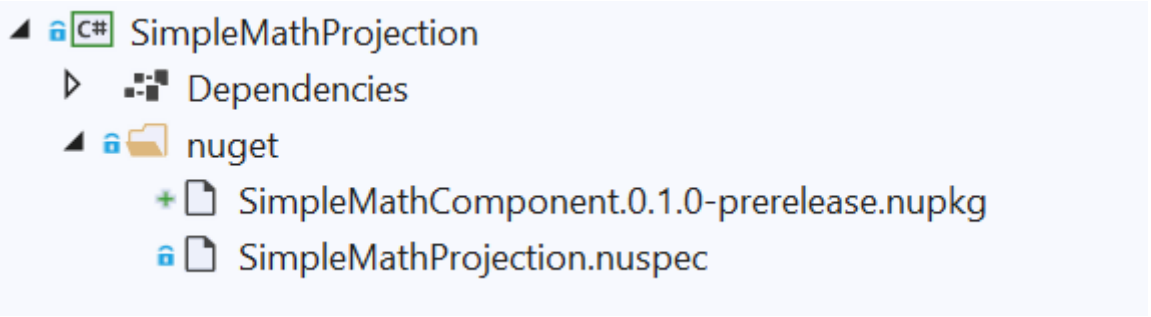
Build the solution to generate the projection and NuGet package

Before building the solution, make sure to check the **Configuration Manager** settings in Visual Studio, under **Build** > **Configuration Manager**. For this walkthrough, set the **Configuration** to **Release** and **Platform** to **x64** for the solution.

At this point you can now build the solution. Right-click on your solution node and select **Build Solution**. This will first build the **SimpleMathComponent** project, and then the **SimpleMathProjection** project. The component WinMD and implementation assembly (**SimpleMathComponent.winmd** and **SimpleMathComponent.dll**), the projection source files, and the projection assembly (**SimpleMathProjection.dll**), will all be generated under the **_build** output directory. You'll also be able to see the generated NuGet package, **SimpleMathComponent0.1.0-prerelease.nupkg**, under the **\SimpleMathProjection\nuget** folder.

> **Important**
>
> If any of the files mentioned above are not generated, then build the solution a second time. You might also need to close and reopen the solution before rebuilding.

You might need to close and reopen the solution for the `.nupkg` to appear in Visual Studio as illustrated (or just select and then deselect **Show All Files**).



Reference the NuGet package in a C# .NET 6 console application

To consume **SimpleMathComponent** from a .NET project, you can simply add to a new .NET project a reference to the **SimpleMathComponent0.1.0-prerelease.nupkg** NuGet package that we created in the previous section. The following steps demonstrate how to do that by creating a simple Console app in a separate solution.

1. Use the steps below to create a new solution containing a C# **Console App** project (creating this project in a new solution allows you to restore the **SimpleMathComponent** NuGet package independently).

   > **ⓘ Important**
   >
   > We'll be creating this new **Console App** project inside the `\CsWinRT\src\Samples\NetProjectionSample` folder, which you'll find in your downloaded or clone of the C#/WinRT projection sample.

   a. In a new instance of Visual Studio, select **File** > **New** > **Project**.
   b. In the **Create a new project** dialog box, search for the **Console App** project template. Choose the C# project template that's called simply **Console App** (with no prefixes nor suffixes), and click **Next**. If you're using Visual Studio 2019, then the project template is **Console Application**.
   c. Name the new project **SampleConsoleApp**, set its location to the same `\CsWinRT\src\Samples\NetProjectionSample` folder that the **SimpleMathComponent** and **SimpleMathProjection** folders are in, and click **Next**.
   d. On the **Additional information** page, select **.NET 6.0 (Long-term support)**, and then choose **Create**.

2. In **Solution Explorer**, double-click the **SampleConsoleApp** node to open the **SampleConsoleApp.csproj** project file, and edit the `TargetFramework` and `Platform` properties so that they look as shown in the following listing. Add the `Platform` element if it's not there.

```
XML

<PropertyGroup>
  <OutputType>Exe</OutputType>
  <TargetFramework>net6.0-windows10.0.19041.0</TargetFramework>
  <Platform>x64</Platform>
</PropertyGroup>
```

3. With the **SampleConsoleApp.csproj** project file still open, we'll next add to the **SampleConsoleApp** project a reference to the **SimpleMathComponent** NuGet package. To restore the **SimpleMathComponent** NuGet when building the project, you can use the `RestoreSources` property with the path to the **nuget** folder in your component solution. Copy the following configuration, and paste it into **SampleConsoleApp.csproj** (inside the `Project` element).

```
XML

<PropertyGroup>
  <RestoreSources>
    https://api.nuget.org/v3/index.json;
    ../SimpleMathProjection/nuget
  </RestoreSources>
</PropertyGroup>

<ItemGroup>
  <PackageReference Include="SimpleMathComponent" Version="0.1.0-
prerelease" />
</ItemGroup>
```

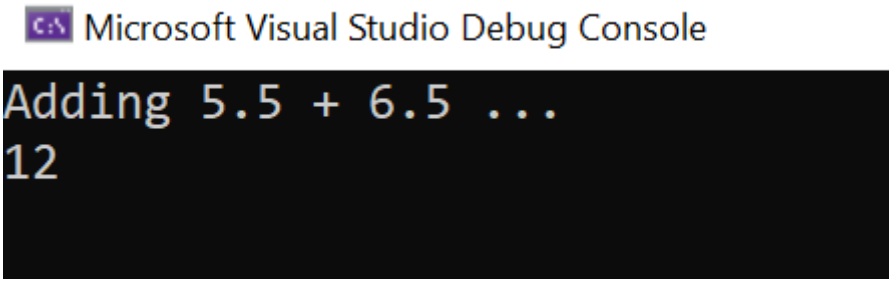
> **ⓘ Important**
>
> The `RestoreSources` path for the **SimpleMathComponent** package shown above is set to `../SimpleMathProjection/nuget`. That path is correct provided that you followed the steps in this walkthrough, so that the **SimpleMathComponent** and **SampleConsoleApp** projects are both in the same folder (the `NetProjectionSample` folder, in this case). If you've done something different, then you'll need to adjust that path accordingly. Alternatively, you can add a local NuGet package feed to your solution.

4. Edit the **Program.cs** file to use the functionality provided by **SimpleMathComponent**.

```
C#

var x = new SimpleMathComponent.SimpleMath();
Console.WriteLine("Adding 5.5 + 6.5 ...");
Console.WriteLine(x.add(5.5, 6.5).ToString());
```

5. Save and close the files you just edited, and build and run the console app. You should see the output below.



Known issues

- When building the projection project, you might see an error like: *Error MSB3271 There was a mismatch between the processor architecture of the project being built "MSIL" and the processor architecture, "x86", of the implementation file "..\SimpleMathComponent.dll" for "..\SimpleMathComponent.winmd". This mismatch may cause runtime failures. Please consider changing the targeted processor architecture of your project through the Configuration Manager so as to align the processor architectures between your project and implementation file, or choose a winmd file with an implementation file that has a processor architecture which matches the targeted processor architecture of your project.* To work around this error, add the following property to your C# library project file:

```
XML

<PropertyGroup>
    <!-- Workaround for MSB3271 error on processor architecture
mismatch -->

<ResolveAssemblyWarnOrErrorOnTargetArchitectureMismatch>None</ResolveAs
semblyWarnOrErrorOnTargetArchitectureMismatch>
</PropertyGroup>
```

Further considerations

The C# projection (or interop) assembly that we showed how to create in this topic is quite simple—it doesn't have dependencies on other components. But to generate a C# projection for a C++/WinRT component that has references to Windows App SDK types, in the projection project you'd need to add a reference to the Windows App SDK NuGet package. If any such references are missing, then you'll see errors such as "Type <T> could not be found".

Another thing that we do in this topic is to distribute the projection as a NuGet package. That *is* currently necessary.

Author Windows Runtime components with C#/WinRT

Article • 10/24/2022

> **Note**
>
> Authoring Windows Runtime components with C#/WinRT is supported on .NET 6 and later.

The C#/WinRT NuGet package provides support for authoring your own Windows Runtime types and components in C#, and consuming them from any Windows Runtime-compatible language such as C++/WinRT or Rust. C#/WinRT authoring and hosting support requires .NET 6 and Visual Studio 2022, and it is intended to support desktop application scenarios including the Windows App SDK, and WinUI3.

For a walkthrough showing how to author a Windows Runtime component with .NET 6, and how to consume it from a C++/WinRT console application, see Walkthrough: Create a C#/WinRT component and consume it from C++/WinRT.

For more details, and to search for or file any issues, refer to the C#/WinRT Github repo and Authoring C#/WinRT Components.

Declaring types in Windows Runtime components

While authoring your Windows Runtime component, follow the guidelines and type restrictions outlined in the existing UWP documentation about Windows Runtime components (see Windows Runtime components with C# and Visual Basic). The component can for the most part be implemented like any other C# library. However, there are restrictions on the public types in the component that will be exposed to the Windows Runtime and declared in the generated `.winmd` for others to consume.

Externally, you can expose only Windows Runtime types for parameters and return values. You can use built-in C# types as part of the public surface of the component as long as there is a mapping from the .NET type to WinRT (see .NET mappings of WinRT types in C#/WinRT), and they will appear to users of the component as the corresponding Windows Runtime types. Windows Runtime types from other Windows Runtime components and the Windows SDK can also be used as part of the public

implementation of the component, such as `in` parameters, return types, and class inheritance.

> **Note**
>
> There are some Windows Runtime types that are mapped to .NET types (see **.NET mappings of WinRT types in C#/WinRT**). These .NET types can be used in the public interface of your Windows Runtime component, and they will appear to users of the component as the corresponding Windows Runtime types.

Walkthrough—Create a C#/WinRT component, and consume it from C++/WinRT

Article • 10/24/2022

C#/WinRT enables developers using .NET to author their own Windows Runtime components in C# using a class library project. Authored components can be consumed in native desktop applications as a package reference or as a project reference with a few modifications.

This walkthrough demonstrates how to create a simple Windows Runtime component using C#/WinRT, distribute the component as a NuGet package, and consume the component from a C++/WinRT console application. For the full sample that provides the code for this article, see the C#/WinRT authoring sample. For more details about authoring, see Authoring components.

For a walkthrough on authoring WinUI controls with C#/WinRT specifically for use in Windows App SDK applications, refer to the article Walkthrough: Author a C# component with WinUI 3 controls and consume from a C++ Windows App SDK application

Prerequisites

This walkthrough requires the following tools and components:

- Visual Studio 2022
- .NET 6.0 SDK or later
- C++/WinRT VSIX for C++/WinRT project templates

Create a simple Windows Runtime Component using C#/WinRT

Begin by creating a new project in Visual Studio. Select the **Class Library** project template, and name the project **AuthoringDemo**. You'll need to make the following additions and modifications to the project:

1. Update the `TargetFramework` in the **AuthoringDemo.csproj** file and add the following elements to the `PropertyGroup`:

XML

```
<PropertyGroup>
    <TargetFramework>net8.0-windows10.0.19041.0</TargetFramework>
    <Platforms>x64</Platforms>
</PropertyGroup>
```

To access Windows Runtime types, you need to set a specific Windows SDK version in the TFM. For more details on the supported version, see .NET 6 and later: Use the TFM option.

2. Install the Microsoft.Windows.CsWinRT NuGet package in your project.

   a. In Solution Explorer, right click on the project node and select **Manage NuGet Packages**.

   b. Search for the **Microsoft.Windows.CsWinRT** NuGet package and install the latest version. This walkthrough uses C#/WinRT version 1.4.1.

3. Add a new `PropertyGroup` element that sets the `CsWinRTComponent` property. This specifies that your project is a Windows Runtime component so that a `.winmd` file is generated when you build the project.

   XML

   ```
   <PropertyGroup>
       <CsWinRTComponent>true</CsWinRTComponent>
   </PropertyGroup>
   ```

   For a full list of C#/WinRT project properties, refer to the C#/WinRT NuGet documentation.

4. You can author your runtime classes using library `.cs` class files. Right click on the `Class1.cs` file, and rename it to `Example.cs`. Add the following code to this file, which adds a public property and method to the runtime class. Remember to mark any classes you want to expose in the runtime component as `public`.

   C#

   ```
   namespace AuthoringDemo
   {
       public sealed class Example
       {
           public int SampleProperty { get; set; }

           public static string SayHello()
   ```

```
        {
            return "Hello from your C# WinRT component";
        }
    }
}
```

5. You can now build the project to generate the `.winmd` file for your component. Right-click on the project in **Solution Explorer**, and click **Build**. You'll see the generated `AuthoringDemo.winmd` file in your build output folder.

Generate a NuGet package for the component

Most developers will want to distribute and share their Windows Runtime component as a NuGet package. Another option is to consume the component as a project reference. The following steps demonstrate how to package the **AuthoringDemo** component. When you generate the package, C#/WinRT configures the component and hosting assemblies in the package to enable consumption from native applications.

There are several ways to generate the NuGet package:

- If you want to generate a NuGet package every time you build the project, add the following property to the **AuthoringDemo** project file and then rebuild the project.

  XML

  ```
  <PropertyGroup>
      <GeneratePackageOnBuild>true</GeneratePackageOnBuild>
  </PropertyGroup>
  ```

- Alternatively, you can generate a NuGet package by right clicking the **AuthoringDemo** project in **Solution Explorer** and selecting **Pack**.

When you build the package, the **Build** window should indicate that the NuGet package `AuthoringDemo.1.0.0.nupkg` was successfully created. See Create a package using the dotnet CLI for more details on NuGet package properties with the .NET CLI.

Consume the component from a C++/WinRT app

C#/WinRT authored Windows Runtime components can be consumed from any Windows Runtime (WinRT)-compatible language. The following steps demonstrate how to call the authored component above in a C++/WinRT console application.

> **Note**
>
> Consuming a C#/WinRT component from C#/.NET apps is supported by both package reference or project reference. This scenario is equivalent to consuming any ordinary C# class library and does not involve WinRT activation in most cases. Starting with C#/WinRT 1.3.5, project references for C# consumers require .NET 6.

1. Add a new **C++/WinRT Console Application** project to your solution. Note that this project can also be part of a different solution if you choose so.

   a. In **Solution Explorer**, right click your solution node and click **Add** -> **New Project**.

   b. In the **Add New Project dialog box**, search for the **C++/WinRT Console Application** project template. Select the template and click **Next**.

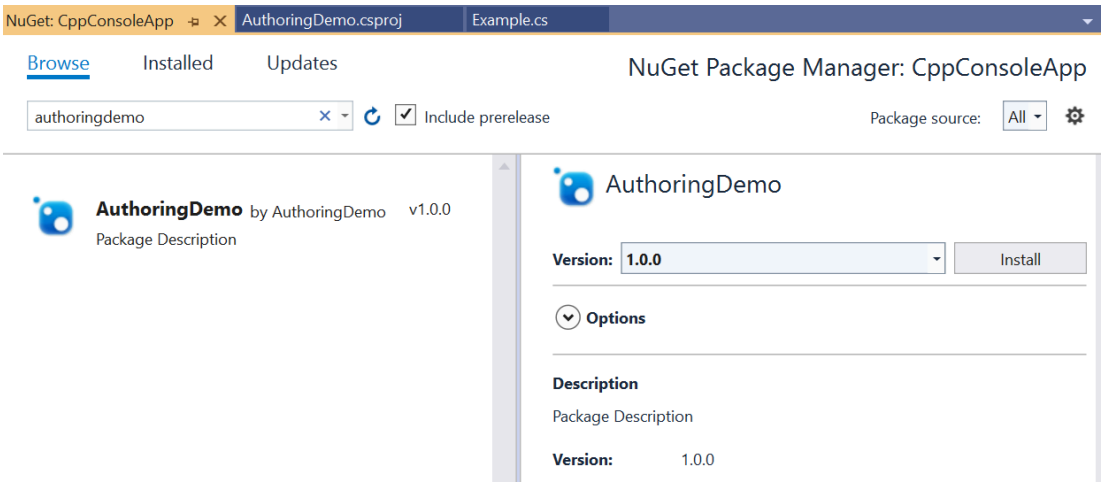
   c. Name the new project **CppConsoleApp** and click **Create**.

2. Add a reference to the AuthoringDemo component, either as a NuGet package or a project reference.

   - **Option 1 (Package reference)**:

     a. Right click the **CppConsoleApp** project and select **Manage NuGet packages**. You may need to configure your package sources to add a reference to the AuthoringDemo NuGet package. To do this, click the **Settings** icon in NuGet Package Manager and add a package source to the appropriate path.

     b. After configuring your package sources, search for the **AuthoringDemo** package and click **Install**.



- **Option 2 (Project reference)**:

  a. Right click the **CppConsoleApp** project and select **Add** -> **Reference**. Under the **Projects** node, add a reference to the **AuthoringDemo** project.

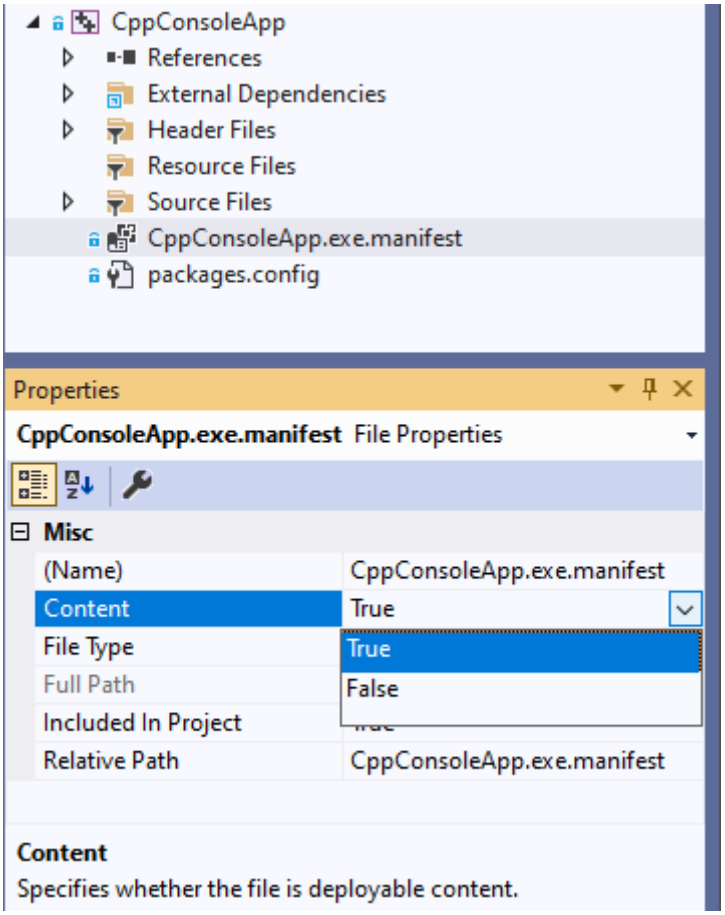
3. To host the component, you will need to add a manifest file for activatable class registrations. For more details about managed component hosting, see Managed component hosting.

   a. To add the manifest file, again right click on the project and choose **Add** -> **New Item**. Search for the **Text File** template and name it **CppConsoleApp.exe.manifest**. Paste the following contents, which specify the runtime classes using activatable class registration entries:

```XML
<?xml version="1.0" encoding="utf-8"?>
<assembly manifestVersion="1.0" xmlns="urn:schemas-microsoft-
com:asm.v1">
    <assemblyIdentity version="1.0.0.0" name="CppConsoleApp"/>
    <file name="WinRT.Host.dll">
        <activatableClass
            name="AuthoringDemo.Example"
            threadingModel="both"
            xmlns="urn:schemas-microsoft-com:winrt.v1" />
    </file>
</assembly>
```

   The application manifest file is required for apps that are not packaged. For packaged apps, the app consumer needs to register the activatable classes in their `Package.appxmanifest` package manifest file, as explained in Walkthrough: Create a C# component with WinUI 3 controls and consume from a C++ Windows App SDK application.

b. Modify the project to include the manifest file in the output when deploying the project. Click the **CppConsoleApp.exe.manifest** file in **Solution Explorer** and set the **Content** property to **True**. Here is an example of what this looks like.



4. Open **pch.h** under the project's Header Files, and add the following line of code to include your component.

```
C++

#include <winrt/AuthoringDemo.h>
```

5. Open **main.cpp** under the project's Source Files, and replace it with the following contents.

```
C++

#include "pch.h"
#include "iostream"

using namespace winrt;
using namespace Windows::Foundation;

int main()
{
    init_apartment();
```

```
    AuthoringDemo::Example ex;
    ex.SampleProperty(42);
    std::wcout << ex.SampleProperty() << std::endl;
    std::wcout << ex.SayHello().c_str() << std::endl;
}
```

6. Build and run the **CppConsoleApp** project. You should now see the output below.

Walkthrough—Create a C# component with WinUI 3 controls, and consume it from a C++/WinRT app that uses the Windows App SDK

Article • 04/19/2023

C#/WinRT provides support for authoring Windows Runtime components, including WinUI custom types and custom controls. These components can be consumed from either C# or C++/WinRT applications that use the Windows App SDK. We recommend using C#/WinRT v1.6.4 or later to author runtime components with NuGet packaging support.

For more details about the supported scenarios, refer to Authoring C#/WinRT components in the C#/WinRT GitHub repo.

This walkthrough demonstrates how to author a C# component with a custom WinUI 3 control, and how to consume that component from a C++/WinRT app, using the Windows App SDK project templates.

Prerequisites

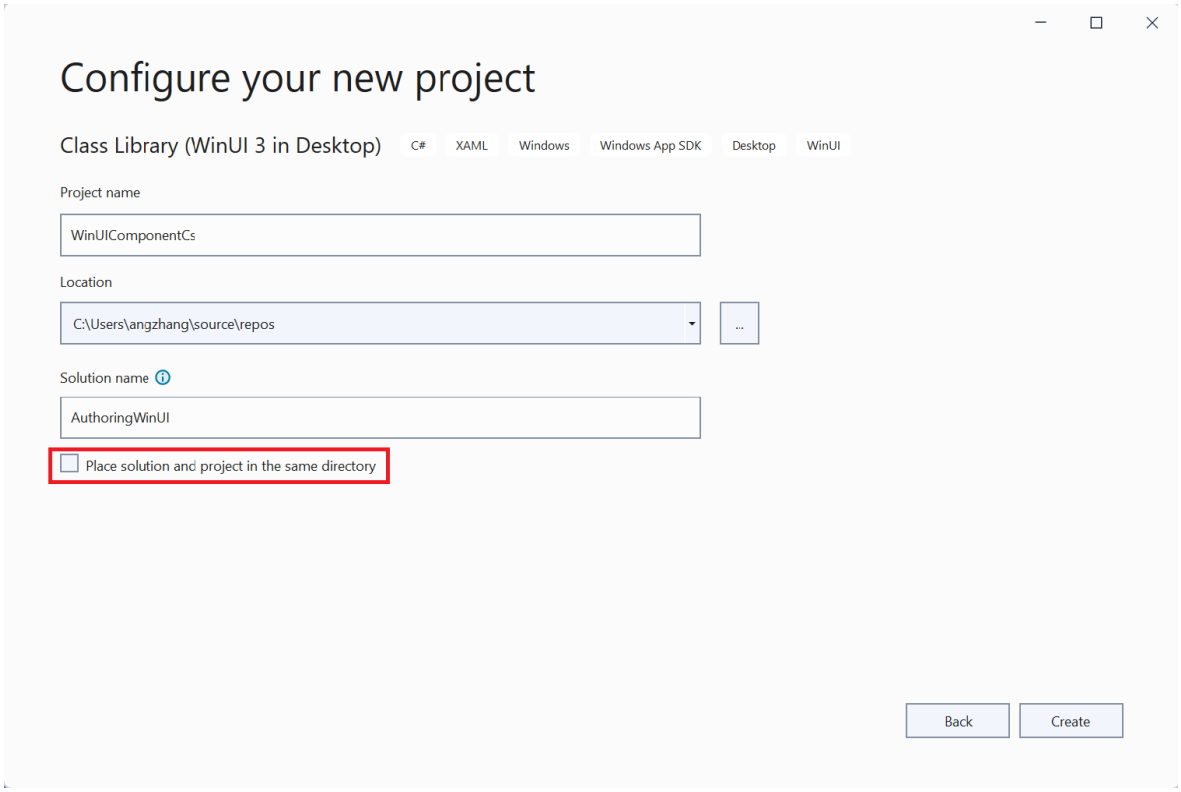
This walkthrough requires the following tools and components:

- Visual Studio 2022
- .NET 6.0 SDK
- Windows App SDK VSIX (1.1 from the stable channel)

Author your C#/WinRT component using the Windows App SDK

1. Create a new C# library project using the **Class Library (WinUI 3 in Desktop)** template provided by the Windows App SDK. For this walkthrough, we've named the library project **WinUIComponentCs**, and the solution **AuthoringWinUI**.

   Leave the **Place solution and project in the same directory** box unchecked (otherwise, the `packages` folder for the C++ application in the preceding section will end up interfering with the C# library project).



2. Delete the `Class1.cs` file that's included by default.

3. Install the latest Microsoft.Windows.CsWinRT NuGet package in your project.

   i. In Solution Explorer, right-click on the project node, and select **Manage NuGet Packages**.

   ii. Search for the **Microsoft.Windows.CsWinRT** NuGet package, and install the latest version.

4. Add the following properties to your library project:

   XML

   ```
   <PropertyGroup>
       <CsWinRTComponent>true</CsWinRTComponent>
   </PropertyGroup>
   ```

   - The `CsWinRTComponent` property specifies that your project is a Windows Runtime component so that a `.winmd` file is generated when you build the project.

5. Add a custom control or user control to your library. To do this, right-click on your project in Visual Studio, click **Add** > **New Item**, and select **WinUI** on the left pane. For this walkthrough, we added a new **User Control (WinUI 3)** and named it `NameReporter.xaml`. The **NameReporter** user control allows a user to enter a first

and last name into the appropriate **TextBox** control, and click a button. The control then displays a message box with the name that the user entered.

6. Paste the following code in the `NameReporter.xaml` file:

XML

```
<UserControl
x:Class="WinUIComponentCs.NameReporter"
xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
xmlns:local="using:WinUIComponentCs"
xmlns:d="http://schemas.microsoft.com/expression/blend/2008"
xmlns:mc="http://schemas.openxmlformats.org/markup-compatibility/2006"
mc:Ignorable="d">

    <StackPanel HorizontalAlignment="Center">
        <StackPanel.Resources>
            <Style x:Key="BasicTextStyle" TargetType="TextBlock"
BasedOn="{StaticResource BodyTextBlockStyle}">
                <Setter Property="Margin" Value="10,10,10,10"/>
            </Style>
        </StackPanel.Resources>

        <TextBlock Text="Enter your name." Margin="0,0,0,10"/>
        <StackPanel Orientation="Horizontal" Margin="0,0,0,10">
            <TextBlock Style="{StaticResource BasicTextStyle}">
                First Name:
            </TextBlock>
            <TextBox Name="firstName" />
        </StackPanel>
        <StackPanel Orientation="Horizontal" Margin="0,0,0,10">
            <TextBlock Style="{StaticResource BasicTextStyle}">
                Last Name:
            </TextBlock>
            <TextBox Name="lastName" />
        </StackPanel>
        <Button Content="Submit" Click="Button_Click"
Margin="0,0,0,10"/>
        <TextBlock Name="result" Style="{StaticResource
BasicTextStyle}" Margin="0,0,0,10"/>
    </StackPanel>
</UserControl>
```

7. Add the following method to `NameReporter.xaml.cs`:

C#

```
using System.Text;
...
private void Button_Click(object sender, RoutedEventArgs e)
{
```

```
    StringBuilder displayText = new StringBuilder("Hello, ");
    displayText.AppendFormat("{0} {1}.", firstName.Text,
lastName.Text);
    result.Text = displayText.ToString();
}
```

8. You can now build the **WinUIComponentCs** project to generate a `.winmd` file for the component.

> **Note**
>
> You can also package the component as a NuGet package for end app consumers to reference. For more details, see **Authoring C#/WinRT components** on the C#/WinRT Github repo.

Reference the component from a Windows App SDK C++/WinRT app

The following steps show how to consume the component created from the previous section from a C++/WinRT Windows App SDK application. Consuming a C#/WinRT component from C++ currently requires using the single-project **Blank App, Packaged (WinUI 3 in Desktop)** template. Note that C# components can also be referenced from C# packaged apps without class registrations.

Consumption from packaged apps that use a separate **Windows Application Packaging (WAP)** project is not currently supported. See Authoring C#/WinRT components in the C#/WinRT GitHub repo for the latest updates on supported project configurations.

1. Add a new C++ Windows App SDK application project to your solution. Right-click on your solution in Visual Studio, and select **Add** > **New Project**. Select the C++ **Blank App, Packaged (WinUI 3 in Desktop)** template provided by the Windows App SDK. For this walkthrough, we named the app **CppApp**.

2. Add a project reference from the C++ app to the C# component. In Visual Studio, right-click on the C++ project and choose **Add** > **Reference**, and select the **WinUIComponentCs** project.

   > **Note**
   >
   > Consuming components as a NuGet package reference is supported with some limitations. Namely, components with custom user controls can't

currently be consumed as a NuGet package reference.

3. In the app's `pch.h` header file, add the following lines:

```C++
#include <winrt/WinUIComponentCs.h>
#include <winrt/WinUIComponentCs.WinUIComponentCs_XamlTypeInfo.h>
```

4. Open up the package manifest file, `Package.appxmanifest`.

> **Note**
>
> There's a known issue where the `Package.appxmanifest` file doesn't appear in Visual Studio Solution Explorer. To workaround that, right-click on your C++ project, select **Unload Project**, and double-click on the project to open the `CppApp.vcxproj` file. Add the following entry to the project file, and then reload the project:

```XML
<ItemGroup>
    <AppxManifest Include="Package.appxmanifest">
    <SubType>Designer</SubType>
    </AppxManifest>
</ItemGroup>
```

In `Package.appxmanifest`, add the following activatable class registrations. You'll also need an additional `ActivatableClass` entry for the **WinUIComponentCs.WinUIComponentCs_XamlTypeInfo.XamlMetaDataProvider** class in order to activate the WinUI types. Right-click on the `Package.appxmanifest` file and select **Open With** > **XML (Text Editor)** in order to edit the file.

```XML
<!--In order to host the C# component from C++, you must add the
following Extension group and list the activatable classes-->
<Extensions>
    <Extension Category="windows.activatableClass.inProcessServer">
        <InProcessServer>
            <Path>WinRT.Host.dll</Path>
            <ActivatableClass
ActivatableClassId="WinUIComponentCs.NameReporter"
ThreadingModel="both" />
```

```
            <ActivatableClass
ActivatableClassId="WinUIComponentCs.WinUIComponentCs_XamlTypeInfo.Xaml
MetaDataProvider" ThreadingModel="both" />
        </InProcessServer>
    </Extension>
</Extensions>
```

5. Open the `MainWindow.xaml` file.

   i. Add a reference to the component's namespace at the top of the file.

   XML

   ```
   xmlns:custom="using:WinUIComponentCs"
   ```

   ii. Add the user control to the existing XAML code.

   XML

   ```
   <StackPanel>
       ...
       <custom:NameReporter/>
   </StackPanel>
   ```

6. Set **CppApp** as the startup project—right-click on **CppApp**, and select **Set as Startup Project**. Set the solution configuration to `x86`. Before building, you might also need to retarget your solution to build with the Visual Studio 2022 build tools. Right-click on the solution, select **Retarget solution**, and upgrade the Platform Toolset to **v143**.

7. Build and run the app to see the custom **NameReporter** control.

Known issues

- Consuming a C# component as a project reference requires `PublishReadyToRun` to be set to `False`. See Github Issue #1151 for more details.
- Consuming a C# component built for `AnyCPU` from C++ is supported only from `x86` applications currently. `x64` and `Arm64` apps result in a runtime error similar to: *%1 is not a valid Win32 application.* See Github Issue #1151 for more details.

Diagnose C#/WinRT component errors

Article • 05/25/2022

This article provides additional information about restrictions on Windows Runtime Components written with C#/WinRT. It expands on the information that is provided in error messages from C#/WinRT when an author builds their component. For existing UWP .NET Native managed components, the metadata for C# WinRT components is generated using Winmdexp.exe, a .NET tool. Now that Windows Runtime support is decoupled from .NET, C#/WinRT provides the tooling to generate a .winmd file from your component. The Windows Runtime has more constraints on code than a C# class library, and the C#/WinRT Diagnostic Scanner alerts you of these before generating a .winmd file.

This article covers the errors reported in your build from C#/WinRT. This article serves as an updated version of the information on restrictions for existing UWP .NET Native managed components which use the Winmdexp.exe tool.

Search for the error message text (omitting specific values for placeholders) or the message number. If you don't find the information you need here, you can help us improve the documentation by using the feedback button at the end of this article. In your feedback, please include the error message. Alternatively, you can file a bug at the C#/WinRT repo.

This article organizes error messages by scenario.

Implementing interfaces that aren't valid Windows Runtime interfaces

C#/WinRT components cannot implement certain Windows Runtime interfaces, such as the Windows Runtime interfaces that represent asynchronous actions or operations (**IAsyncAction**, **IAsyncActionWithProgress<TProgress>**, **IAsyncOperation<TResult>**, or **IAsyncOperationWithProgress<TResult,TProgress>**). Instead, use the **AsyncInfo** class for generating async operations in Windows Runtime components. Note: these are not the only invalid interfaces, for example a class cannot implement **System.Exception**.

Error number	Message text
CsWinRT1008	Windows Runtime component type {0} cannot implement interface {1}, as the interface is not a valid Windows Runtime interface

Attribute related errors

In the Windows Runtime, overloaded methods can have the same number of parameters only if one overload is specified as the default overload. Use the attribute **Windows.Foundation.Metadata.DefaultOverload** (CsWinRT1015, 1016).

When arrays are used as inputs or outputs in either functions or properties, they must be either read-only or write-only (CsWinRT 1025). The attributes **System.Runtime.InteropServices.WindowsRuntime.ReadOnlyArray** and **System.Runtime.InteropServices.WindowsRuntime.WriteOnlyArray** are provided for you to use. The provided attributes are only for use on parameters of the array type (CsWinRT1026), and only one should be applied per parameter (CsWinRT1023).

You do not need to apply any attribute to an array parameter marked **out**, as it is assumed to be write-only. There is an error message if you decorate it as read-only in this case (CsWinRT1024).

The attributes **System.Runtime.InteropServices.InAttribute** and **System.Runtime.InteropServices.OutAttribute** should not be used on parameters of any type (CsWinRT1021,1022).

Error number	Message text
CsWinRT1015	In class {2}: Multiple {0}-parameter overloads of '{1}' are decorated with Windows.Foundation.Metadata.DefaultOverloadAttribute. The attribute may only be applied to one overload of the method.
CsWinRT1016	In class {2}: The {0}-parameter overloads of {1} must have exactly one method specified as the default overload by decorating it with the attribute Windows.Foundation.Metadata.DefaultOverloadAttribute.
CsWinRT1021	Method '{0}' has parameter '{1}' which is an array, and which has either a System.Runtime.InteropServices.InAttribute or a System.Runtime.InteropServices.OutAttribute. In the Windows Runtime, array parameters must have either ReadOnlyArray or WriteOnlyArray. Please remove these attributes or replace them with the appropriate Windows Runtime attribute if necessary.
CsWinRT1022	Method '{0}' has parameter '{1}' with a System.Runtime.InteropServices.InAttribute or System.Runtime.InteropServices.OutAttribute.Windows Runtime does not support marking parameters with System.Runtime.InteropServices.InAttribute or System.Runtime.InteropServices.OutAttribute. Please consider removing System.Runtime.InteropServices.InAttribute and replace System.Runtime.InteropServices.OutAttribute with 'out' modifier instead.

Error number	Message text
CsWinRT1023	Method '{0}' has parameter '{1}' which is an array, and which has both ReadOnlyArray and WriteOnlyArray. In the Windows Runtime, the contents array parameters must be either readable or writable. Please remove one of the attributes from '{1}'.
CsWinRT1024	Method '{0}' has an output parameter '{1}' which is an array, but which has ReadOnlyArray attribute. In the Windows Runtime, the contents of output arrays are writable. Please remove the attribute from '{1}'.
CsWinRT1025	Method '{0}' has parameter '{1}' which is an array. In the Windows Runtime, the contents of array parameters must be either readable or writable. Please apply either ReadOnlyArray or WriteOnlyArray to '{1}'.
CsWinRT1026	Method '{0}' has parameter '{1}' which is not an array, and which has either a ReadOnlyArray attribute or a WriteOnlyArray attribute. Windows Runtime does not support marking non-array parameters with ReadOnlyArray or WriteOnlyArray."

Namespace errors and invalid names for the output file

In the Windows Runtime, all the public types in a Windows metadata (.winmd) file must be in a namespace that shares the .winmd file name, or in sub-namespaces of the file name. For example, if your Visual Studio project is named A.B (that is, your Windows Runtime component is A.B.winmd), it can contain public classes A.B.Class1 and A.B.C.Class2, but not A.Class3 or D.Class4.

> ⓘ **Note**
>
> These restrictions apply only to public types, not to private types used in your implementation.

In the case of A.Class3, you can either move Class3 to another namespace or change the name of the Windows Runtime component to A.winmd. In the previous example, code that calls A.B.winmd will be unable to locate A.Class3.

In the case of D.Class4, no file name can contain both D.Class4 and classes in the A.B namespace, so changing the name of the Windows Runtime component is not an option. You can either move D.Class4 to another namespace, or put it in another Windows Runtime component.

The file system can't distinguish between uppercase and lowercase, so namespaces that differ by case are not allowed (CsWinRT1002).

Error number	Message text
CsWinRT1001	A public type has a namespace ('{1}') that shares no common prefix with other namespaces ('{0}'). All types within a Windows Metadata file must exist in a sub namespace of the namespace that is implied by the file name.
CsWinRT1002	Multiple namespaces found with the name '{0}'; namespace names cannot differ only by case in the Windows Runtime.

Exporting types that aren't valid Windows Runtime types

The public interface of your component must expose only Windows Runtime types. However, .NET provides mappings for a number of commonly used types that are slightly different in .NET and the Windows Runtime. This enables the .NET developer to work with familiar types instead of learning new ones. You can use these mapped .NET Framework types in the public interface of your component. For more information, see Declaring types in Windows Runtime Components, Passing Windows Runtime types to managed code, and .NET mappings of Windows Runtime types.

Many of these mappings are interfaces. For example, IList<T> maps to the Windows Runtime interface IVector<T>. If you use List<string> instead of IList<string> as a parameter type, C#/WinRT provides a list of alternatives that includes all the mapped interfaces implemented by List<T>. If you use nested generic types, such as List<Dictionary<int, string>>, C#/WinRT offers choices for each level of nesting. These lists can become quite long.

In general, the best choice is the interface that is closest to the type. For example, for Dictionary<int, string>, the best choice is most likely IDictionary<int, string>.

Error number	Message text
CsWinRT1006	The member '{0}' has the type '{1}' in its signature. The type '{1}' is not a valid Windows Runtime type. Yet, the type (or its generic parameters) implement interfaces that are valid Windows Runtime types. Consider changing the type '{1} in the member signature to one of the following types from System.Collections.Generic: {2}.

In the Windows Runtime, arrays in member signatures must be one-dimensional with a lower bound of 0 (zero). Nested array types such as `myArray[][]` (CsWinRT1017) and `myArray[,]` (CsWinRT1018) are not allowed.

> **Note**
>
> This restriction does not apply to arrays you use internally in your implementation.

Error number	Message text
CsWinRT1017	Method {0} has a nested array of type {1} in its signature. Arrays in Windows Runtime method signature cannot be nested.
CsWinRT1018	Method '{0}' has a multi-dimensional array of type '{1}' in its signature. Arrays in Windows Runtime method signatures must be one dimensional.

Structures that contain fields of disallowed types

In the Windows Runtime, a structure can contain only fields, and only structures can contain fields. Those fields must be public. Valid field types include enumerations, structures, and primitive types.

Error number	Message text
CsWinRT1007	Structure {0} contains no public fields. Windows Runtime structures must contain at least one public field.
CsWinRT1011	Structure {0} has non-public field. All fields must be public for Windows Runtime structures.
CsWinRT1012	Structure {0} has const field. Constants can only appear on Windows Runtime enumerations.
CsWinRT1013	Structure {0} has field of type {1}; {1} is not a valid Windows Runtime field type. Each field in a Windows Runtime structure can only be UInt8, Int16, UInt16, Int32, UInt32, Int64, UInt64, Single, Double, Boolean, String, Enum, or itself a structure.

Parameter name conflicts with generated code

In the Windows Runtime, return values are considered to be output parameters, and the names of parameters must be unique. By default, C#/WinRT gives the return value the name `__retval`. If your method has a parameter named `__retval`, you will get error CsWinRT1010. To correct this, give your parameter a name other than `__retvalue`.

Error number	Message text
CsWinRT1010	The parameter name {1} in method {0} is the same as the return value parameter name used in the generated C#/WinRT interop; use a different parameter name.

Miscellaneous

Other restrictions in a C#/WinRT authored component include:

- You cannot expose overloaded operators on public types.
- Classes and interfaces cannot be generic.
- Classes must be sealed.
- Parameters cannot be passed by reference, e.g. using the **ref** keyword.
- Properties must have a public get method.
- There must be at least one public type (class or interface) in your component's namespace.

Error number	Message text
CsWinRT1014	'{0}' is an operator overload. Managed types cannot expose operator overloads in the Windows Runtime.
CsWinRT1004	Type {0} is generic. Windows Runtime types cannot be generic.
CsWinRT1005	Exporting unsealed types is not supported in CsWinRT. Please mark type {0} as sealed.
CsWinRT1020	Method '{0}' has parameter '{1}' marked `ref`. Reference parameters are not allowed in Windows Runtime.
CsWinRT1000	Property '{0}' does not have a public getter method. Windows Runtime does not support setter-only properties.
CsWinRT1003	Windows Runtime components must have at least one public type

In the Windows Runtime, a class can have only one constructor with a given number of parameters. For example, you can't have one constructor that has a single parameter of

type **string** and another constructor that has a single parameter of type **int**. The only workaround is to use a different number of parameters for each constructor.

Error number	Message text
CsWinRT1009	Classes cannot have multiple constructors of the same arity in the Windows Runtime, class {0} has multiple {1}-arity constructors.

Using brushes to paint backgrounds, foregrounds, and outlines

Article • 11/26/2024

Use **Brush** objects to paint the interiors and outlines of XAML shapes, text, and controls, making them visible in your application UI.

> **Important APIs**: Brush class

Introduction to brushes

To paint a **Shape**, text, or parts of a **Control** that is displayed on the app canvas, set the **Fill** property of the **Shape** or the **Background** and **Foreground** properties of a **Control** to a **Brush** value.

The different types of brushes are:

- **AcrylicBrush**
- **SolidColorBrush**
- **LinearGradientBrush**
- **RadialGradientBrush**
- **ImageBrush**
- **WebViewBrush**
- **XamlCompositionBrushBase**

Solid color brushes

A **SolidColorBrush** paints an area with a single **Color**, such as red or blue. This is the most basic brush. In XAML, there are three ways to define a **SolidColorBrush** and the color it specifies: predefined color names, hexadecimal color values, or the property element syntax.

Predefined color names

You can use a predefined color name, such as **Yellow** or **Magenta**. There are 256 available named colors. The XAML parser converts the color name to a **Color** structure with the correct color channels. The 256 named colors are based on the *X11* color names from the Cascading Style Sheets, Level 3 (CSS3) specification, so you may already

be familiar with this list of named colors if you have previous experience with web development or design.

Here's an example that sets the **Fill** property of a **Rectangle** to the predefined color **Red**.

XAML

```
<Rectangle Width="100" Height="100" Fill="Red" />
```

SolidColorBrush applied to a Rectangle

If you are defining a **SolidColorBrush** using code rather than XAML, each named color is available as a static property value of the **Colors** class. For example, to declare a **Color** value of a **SolidColorBrush** to represent the named color "Orchid", set the **Color** value to the static value **Colors.Orchid**.

Hexadecimal color values

You can use a hexadecimal format string to declare precise 24-bit color values with 8-bit alpha channel for a **SolidColorBrush**. Two characters in the range 0 to F define each component value, and the component value order of the hexadecimal string is: alpha channel (opacity), red channel, green channel, and blue channel (**ARGB**). For example, the hexadecimal value "#FFFF0000" defines fully opaque red (alpha="FF", red="FF", green="00", and blue="00").

This XAML example sets the **Fill** property of a **Rectangle** to the hexadecimal value "#FFFF0000", and gives an identical result to using the named color **Colors.Red**.

XML

```
<StackPanel>
  <Rectangle Width="100" Height="100" Fill="#FFFF0000" />
</StackPanel>
```

Property element syntax

You can use property element syntax to define a **SolidColorBrush**. This syntax is more verbose than the previous methods, but you can specify additional property values on an element, such as the **Opacity**. For more info on XAML syntax, including property element syntax, see the XAML overview and XAML syntax guide.

In the previous examples, the brush being created is created implicitly and automatically, as part of a deliberate XAML language shorthand that helps keep UI definitions simple for the most common cases. The next example creates a **Rectangle** and explicitly creates the **SolidColorBrush** as an element value for a **Rectangle.Fill** property. The **Color** of the **SolidColorBrush** is set to **Blue** and the **Opacity** is set to 0.5.

XML

```
<Rectangle Width="200" Height="150">
    <Rectangle.Fill>
        <SolidColorBrush Color="Blue" Opacity="0.5" />
    </Rectangle.Fill>
</Rectangle>
```

Linear gradient brushes

A **LinearGradientBrush** paints an area with a gradient that's defined along a line. This line is called the *gradient axis*. You specify the gradient's colors and their locations along the gradient axis using **GradientStop** objects. By default, the gradient axis runs from the upper left corner to the lower right corner of the area that the brush paints, resulting in a diagonal shading.

The **GradientStop** is the basic building block of a gradient brush. A gradient stop specifies what the **Color** of the brush is at an **Offset** along the gradient axis, when the brush is applied to the area being painted.

The gradient stop's **Color** property specifies the color of the gradient stop. You can set the color by using a predefined color name or by specifying the hexadecimal **ARGB** values.

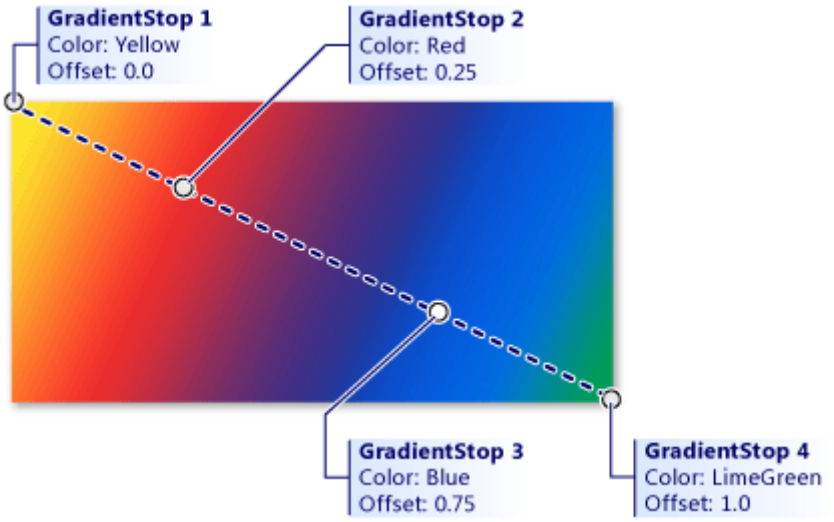
The **Offset** property of a **GradientStop** specifies the position of each **GradientStop** along the gradient axis. The **Offset** is a **double** that ranges from 0 to 1. An **Offset** of 0 places the **GradientStop** at the start of the gradient axis, in other words near its **StartPoint**. An **Offset** of 1 places the **GradientStop** at the **EndPoint**. At a minimum, a useful **LinearGradientBrush** should have two **GradientStop** values, where each **GradientStop** should specify a different **Color** and have a different **Offset** between 0 and 1.

This example creates a linear gradient with four colors and uses it to paint a Rectangle.

XML

```
<!-- This rectangle is painted with a diagonal linear gradient. -->
<Rectangle Width="200" Height="100">
    <Rectangle.Fill>
        <LinearGradientBrush StartPoint="0,0" EndPoint="1,1">
            <GradientStop Color="Yellow" Offset="0.0"
x:Name="GradientStop1"/>
            <GradientStop Color="Red" Offset="0.25" x:Name="GradientStop2"/>
            <GradientStop Color="Blue" Offset="0.75"
x:Name="GradientStop3"/>
            <GradientStop Color="LimeGreen" Offset="1.0"
x:Name="GradientStop4"/>
        </LinearGradientBrush>
    </Rectangle.Fill>
</Rectangle>
```

The color of each point between gradient stops is linearly interpolated as a combination of the color specified by the two bounding gradient stops. The following image highlights the gradient stops in the previous example. The circles mark the position of the gradient stops, and the dashed line shows the gradient axis.



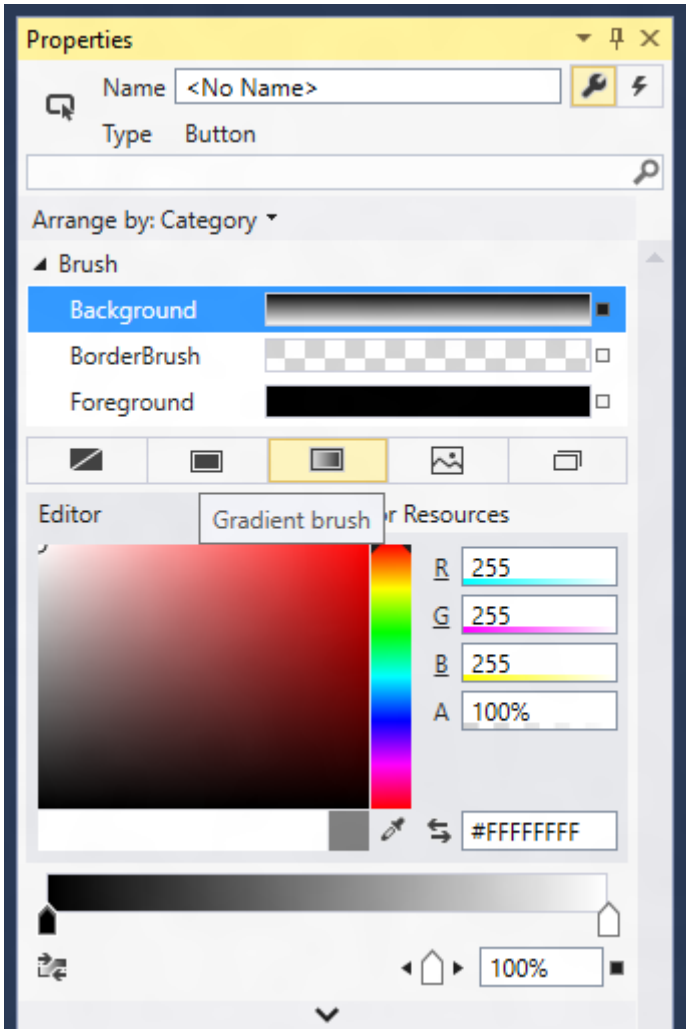
Combination of colors specified by the two bounding gradient stops

You can change the line at which the gradient stops are positioned by setting the StartPoint and EndPoint properties to be different values than the `(0,0)` and `(1,1)` starting defaults. By changing the **StartPoint** and **EndPoint** coordinate values, you can create horizontal or vertical gradients, reverse the gradient direction, or condense the gradient spread to apply to a smaller range than the full painted area. To condense the gradient, you set values of **StartPoint** and/or **EndPoint** to be something that is between the values 0 and 1. For example, if you want a horizontal gradient where the fade all

happens on the left half of the brush and the right side is solid to your last GradientStop color, you specify a **StartPoint** of `(0,0)` and an **EndPoint** of `(0.5,0)`.

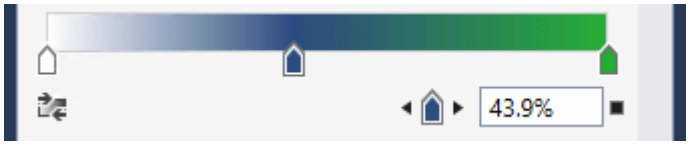
Use tools to make gradients

Now that you know how linear gradients work, you can use Visual Studio or Blend to make creating these gradients easier. To create a gradient, select the object you want to apply a gradient to on the design surface or in XAML view. Expand **Brush** and select the **Linear Gradient** tab.



Creating a linear gradient in Visual Studio

Now you can change the colors of the gradient stops and slide their positions using the bar on the bottom. You can also add new gradient stops by clicking on the bar and remove them by dragging the stops off of the bar (see next screenshot).



Gradient setting slider

Radial gradient brushes

A **RadialGradientBrush** is drawn within an ellipse that is defined by the **Center**, **RadiusX**, and **RadiusY** properties. Colors for the gradient start at the center of the ellipse and end at the radius.

The colors for the radial gradient are defined by color stops added to the **GradientStops** collection property. Each gradient stop specifies a color and an offset along the gradient.

The gradient origin defaults to center and can be offset using the **GradientOrigin** property.

MappingMode defines whether **Center**, **RadiusX**, **RadiusY**, and **GradientOrigin** represent relative or absolute coordinates.

When **MappingMode** is set to `RelativeToBoundingBox`, the X and Y values of the three properties are treated as relative to the element bounds, where `(0,0)` represents the top left and `(1,1)` represents the bottom right of the element bounds for the **Center**, **RadiusX**, and **RadiusY** properties and `(0,0)` represents the center for the **GradientOrigin** property.

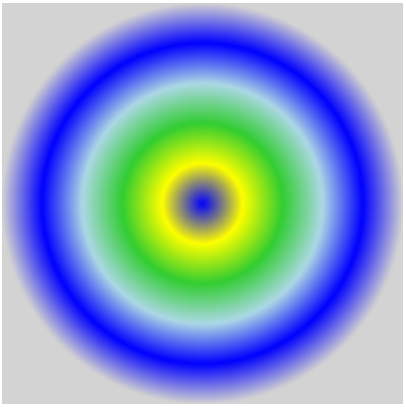
When **MappingMode** is set to `Absolute`, the X and Y values of the three properties are treated as absolute coordinates within the element bounds.

This example creates a linear gradient with four colors and uses it to paint a **Rectangle**.

XML

```
<!-- This rectangle is painted with a radial gradient. -->
<Rectangle Width="200" Height="200">
    <Rectangle.Fill>
        <media:RadialGradientBrush>
            <GradientStop Color="Blue" Offset="0.0" />
            <GradientStop Color="Yellow" Offset="0.2" />
            <GradientStop Color="LimeGreen" Offset="0.4" />
            <GradientStop Color="LightBlue" Offset="0.6" />
            <GradientStop Color="Blue" Offset="0.8" />
            <GradientStop Color="LightGray" Offset="1" />
        </media:RadialGradientBrush>
    </Rectangle.Fill>
</Rectangle>
```

The color of each point between gradient stops is radially interpolated as a combination of the color specified by the two bounding gradient stops. The following image highlights the gradient stops in the previous example.



Gradient stops

Image brushes

An **ImageBrush** paints an area with an image, with the image to paint coming from an image file source. You set the **ImageSource** property with the path of the image to load. Typically, the image source comes from a **Content** item that is part of your app's resources.

By default, an **ImageBrush** stretches its image to completely fill the painted area, possibly distorting the image if the painted area has a different aspect ratio than the image. You can change this behavior by changing the **Stretch** property from its default value of **Fill** and setting it as **None**, **Uniform**, or **UniformToFill**.

The next example creates an **ImageBrush** and sets the **ImageSource** to an image named licorice.jpg, which you must include as a resource in the app. The **ImageBrush** then paints the area defined by an **Ellipse** shape.

XML

```
<Ellipse Height="200" Width="300">
   <Ellipse.Fill>
     <ImageBrush ImageSource="licorice.jpg" />
   </Ellipse.Fill>
</Ellipse>
```

A rendered ImageBrush

ImageBrush and **Image** both reference an image source file by Uniform Resource Identifier (URI), where that image source file uses several possible image formats. These image source files are specified as URIs. For more info about specifying image sources, the usable image formats, and packaging them in an app, see Image and ImageBrush.

Brushes and text

You can also use brushes to apply rendering characteristics to text elements. For example, the **Foreground** property of **TextBlock** takes a **Brush**. You can apply any of the brushes described here to text. However, be careful with brushes applied to text, as any background might make the text can be unreadable if you use brushes that bleed into the background. Use **SolidColorBrush** for readability of text elements in most cases, unless you want the text element to be mostly decorative.

Even when you use a solid color, make sure that the text color you choose has enough contrast against the background color of the text's layout container. The level of contrast between text foreground and text container background is an accessibility consideration.

WebViewBrush

A **WebViewBrush** is a special type of brush that can access the content normally viewed in a **WebView** control. Instead of rendering the content in the rectangular **WebView** control area, **WebViewBrush** paints that content onto another element that has a **Brush**-type property for a render surface. **WebViewBrush** isn't appropriate for every brush scenario, but is useful for transitions of a **WebView**. For more info, see **WebViewBrush**.

XamlCompositionBrushBase

XamlCompositionBrushBase is a base class used to create custom brushes that use CompositionBrush to paint XAML UI elements.

This enables "drop down" interoperation between the Windows.UI.Xaml and Windows.UI.Composition layers as described in the Visual Layer overview.

To create a custom brush, create a new class that inherits from XamlCompositionBrushBase and implements the required methods.

For example, this can be used to apply effects to XAML UIElements using a CompositionEffectBrush, such as a **GaussianBlurEffect** or a SceneLightingEffect that controls the reflective properties of a XAML UIElement when being lit by a XamlLight.

For code examples, see XamlCompositionBrushBase.

Brushes as XAML resources

You can declare any brush to be a keyed XAML resource in a XAML resource dictionary. This makes it easy to replicate the same brush values as applied to multiple elements in a UI. The brush values are then shared and applied to any case where you reference the brush resource as a {StaticResource} usage in your XAML. This includes cases where you have a XAML control template that references the shared brush, and the control template is itself a keyed XAML resource.

Brushes in code

It's much more typical to specify brushes using XAML than it is to use code to define brushes. This is because brushes are usually defined as XAML resources, and because brush values are often the output of design tools or otherwise as part of a XAML UI definition. Still, for the occasional case where you might want to define a brush using code, all the Brush types are available for code instantiation.

To create a SolidColorBrush in code, use the constructor that takes a Color parameter. Pass a value that is a static property of the Colors class, like this:

cs

```
SolidColorBrush blueBrush = new SolidColorBrush(Windows.UI.Colors.Blue);
```

VB

```
Dim blueBrush as SolidColorBrush = New
```

```
SolidColorBrush(Windows.UI.Colors.Blue)
```

C++/WinRT

```
Windows::UI::Xaml::Media::SolidColorBrush blueBrush{
Windows::UI::Colors::Blue() };
```

C++

```
blueBrush = ref new SolidColorBrush(Windows::UI::Colors::Blue);
```

For **WebViewBrush** and **ImageBrush**, use the default constructor and then call other APIs before you attempt to use that brush for a UI property.

- **ImageSource** requires a **BitmapImage** (not a URI) when you define an **ImageBrush** using code. If your source is a stream , use the **SetSourceAsync** method to initialize the value. If your source is a URI, which includes content in your app that uses the **ms-appx** or **ms-resource** schemes, use the **BitmapImage** constructor that takes a URI. You might also consider handling the **ImageOpened** event if there are any timing issues with retrieving or decoding the image source, where you might need alternate content to display until the image source is available.
- For **WebViewBrush** you might need to call **Redraw** if you've recently reset the **SourceName** property or if the content of the **WebView** is also being changed with code.

For code examples, see **WebViewBrush**, **ImageBrush**, and **XamlCompositionBrushBase**.

XAML styles

Article • 11/26/2024

You can customize the appearance of your apps in many ways by using the XAML framework. Styles let you set control properties and reuse those settings for a consistent appearance across multiple controls.

WinUI and styles

Starting with WinUI 2.2, we have used WinUI to deliver new visual style updates across our UI components. If you notice your UI is not updating to the latest styles, be sure to update to the latest WinUI NuGet package.

Starting with WinUI 2.6, we provide new styles for most of the controls, and a new versioning system that let's you revert to the previous control styles if needed. We encourage you to use the new styles, as they better match the design direction of Windows. However, if your scenario cannot support the new styles, the previous versions are still available.

You can change the style version by setting the `ControlsResourcesVersion` property on the `XamlControlsResources` that you include in your `Application.Resources` when you use WinUI version 2. `ControlsResourcesVersion` defaults to the enum value `Version2`.

Setting this value to `Version1` causes `XamlControlsResources` to load the previous style versions instead of the new styles used by the latest WinUI version. Changing this property at runtime is not supported and VisualStudio's hot reload functionality will not work; however, after you rebuild your application you will see the control styles change.

XAML

```
<Application.Resources>
    <XamlControlsResources xmlns="using:Microsoft.UI.Xaml.Controls"
                           ControlsResourcesVersion="Version1"/>
</Application.Resources>
```

Style basics

Use styles to extract visual property settings into reusable resources. Here's an example that shows 3 buttons with a style that sets the BorderBrush, BorderThickness and

Foreground properties. By applying a style, you can make the controls appear the same without having to set these properties on each control separately.

You can define a style inline in the XAML for a control, or as a reusable resource. Define resources in an individual page's XAML file, in the App.xaml file, or in a separate resource dictionary XAML file. A resource dictionary XAML file can be shared across apps, and more than one resource dictionary can be merged in a single app. Where the resource is defined determines the scope in which it can be used. Page-level resources are available only in the page where they are defined. If resources with the same key are defined in both App.xaml and in a page, the resource in the page overrides the resource in App.xaml. If a resource is defined in a separate resource dictionary file, its scope is determined by where the resource dictionary is referenced.

In the Style definition, you need a TargetType attribute and a collection of one or more Setter elements. The **TargetType** attribute is a string that specifies a FrameworkElement type to apply the style to. The **TargetType** value must specify a **FrameworkElement**-derived type that's defined by the Windows Runtime or a custom type that's available in a referenced assembly. If you try to apply a style to a control and the control's type doesn't match the **TargetType** attribute of the style you're trying to apply, an exception occurs.

Each Setter element requires a Property and a Value. These property settings indicate what control property the setting applies to, and the value to set for that property. You can set the **Setter.Value** with either attribute or property element syntax. The XAML here shows the style applied to the buttons shown previously. In this XAML, the first two **Setter** elements use attribute syntax, but the last **Setter**, for the BorderBrush property, uses property element syntax. The example doesn't use the x:Key attribute attribute, so the style is implicitly applied to the buttons. Applying styles implicitly or explicitly is explained in the next section.

XAML

```
<Page.Resources>
    <Style TargetType="Button">
        <Setter Property="BorderThickness" Value="5" />
        <Setter Property="Foreground" Value="Black" />
        <Setter Property="BorderBrush" >
            <Setter.Value>
                <LinearGradientBrush StartPoint="0.5,0" EndPoint="0.5,1">
                    <GradientStop Color="Yellow" Offset="0.0" />
                    <GradientStop Color="Red" Offset="0.25" />
                    <GradientStop Color="Blue" Offset="0.75" />
```

```
                    <GradientStop Color="LimeGreen" Offset="1.0" />
                </LinearGradientBrush>
            </Setter.Value>
        </Setter>
    </Style>
</Page.Resources>

<StackPanel Orientation="Horizontal">
    <Button Content="Button"/>
    <Button Content="Button"/>
    <Button Content="Button"/>
</StackPanel>
```

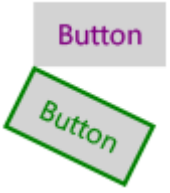
Apply an implicit or explicit style

If you define a style as a resource, there are two ways to apply it to your controls:

- Implicitly, by specifying only a TargetType for the Style.
- Explicitly, by specifying a TargetType and an x:Key attribute attribute for the Style and then by setting the target control's Style property with a {StaticResource} markup extension reference that uses the explicit key.

If a style contains the x:Key attribute, you can only apply it to a control by setting the Style property of the control to the keyed style. In contrast, a style without an x:Key attribute is automatically applied to every control of its target type, that doesn't otherwise have an explicit style setting.

Here are two buttons that demonstrate implicit and explicit styles.



In this example, the first style has an x:Key attribute and its target type is Button. The first button's Style property is set to this key, so this style is applied explicitly. The second style is applied implicitly to the second button because its target type is **Button** and the style doesn't have an x:Key attribute.

XAML

```
<Page.Resources>
    <Style x:Key="PurpleStyle" TargetType="Button">
        <Setter Property="FontFamily" Value="Segoe UI"/>
        <Setter Property="FontSize" Value="14"/>
        <Setter Property="Foreground" Value="Purple"/>
```

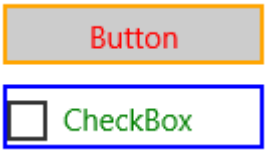
```
    </Style>

    <Style TargetType="Button">
        <Setter Property="FontFamily" Value="Segoe UI"/>
        <Setter Property="FontSize" Value="14"/>
        <Setter Property="RenderTransform">
            <Setter.Value>
                <RotateTransform Angle="25"/>
            </Setter.Value>
        </Setter>
        <Setter Property="BorderBrush" Value="Green"/>
        <Setter Property="BorderThickness" Value="2"/>
        <Setter Property="Foreground" Value="Green"/>
    </Style>
</Page.Resources>

<Grid x:Name="LayoutRoot">
    <Button Content="Button" Style="{StaticResource PurpleStyle}"/>
    <Button Content="Button"/>
</Grid>
```

Use based-on styles

To make styles easier to maintain and to optimize style reuse, you can create styles that inherit from other styles. You use the BasedOn property to create inherited styles. Styles that inherit from other styles must target the same type of control or a control that derives from the type targeted by the base style. For example, if a base style targets ContentControl, styles that are based on this style can target **ContentControl** or types that derive from **ContentControl** such as Button and ScrollViewer. If a value is not set in the based-on style, it's inherited from the base style. To change a value from the base style, the based-on style overrides that value. The next example shows a **Button** and a CheckBox with styles that inherit from the same base style.



The base style targets ContentControl, and sets the Height, and Width properties. The styles based on this style target CheckBox and Button, which derive from **ContentControl**. The based-on styles set different colors for the BorderBrush and Foreground properties. (You don't typically put a border around a **CheckBox**. We do it here to show the effects of the style.)

XAML

```
<Page.Resources>
    <Style x:Key="BasicStyle" TargetType="ContentControl">
        <Setter Property="Width" Value="130" />
        <Setter Property="Height" Value="30" />
    </Style>

    <Style x:Key="ButtonStyle" TargetType="Button"
           BasedOn="{StaticResource BasicStyle}">
        <Setter Property="BorderBrush" Value="Orange" />
        <Setter Property="BorderThickness" Value="2" />
        <Setter Property="Foreground" Value="Red" />
    </Style>

    <Style x:Key="CheckBoxStyle" TargetType="CheckBox"
           BasedOn="{StaticResource BasicStyle}">
        <Setter Property="BorderBrush" Value="Blue" />
        <Setter Property="BorderThickness" Value="2" />
        <Setter Property="Foreground" Value="Green" />
    </Style>
</Page.Resources>

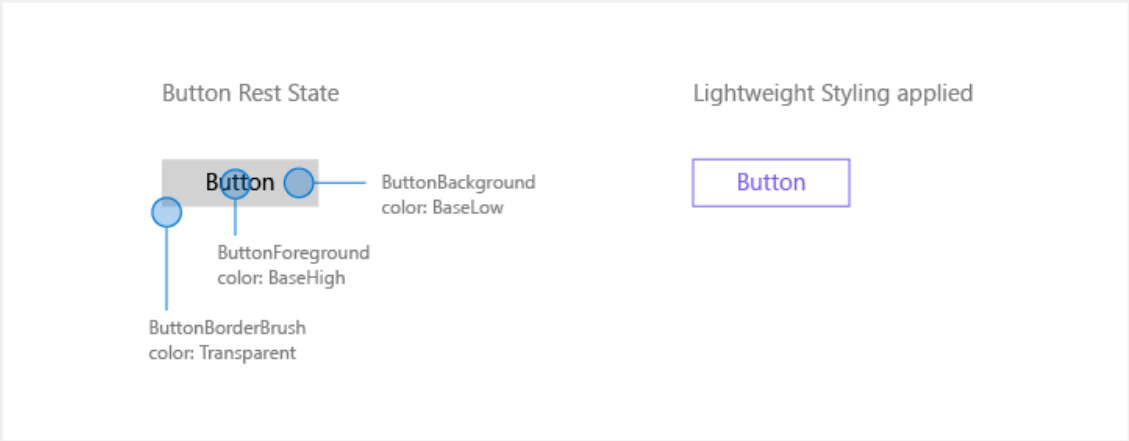
<StackPanel>
    <Button Content="Button" Style="{StaticResource ButtonStyle}"
Margin="0,10"/>
    <CheckBox Content="CheckBox" Style="{StaticResource CheckBoxStyle}"/>
</StackPanel>
```

Use tools to work with styles easily

A fast way to apply styles to your controls is to right-click on a control on the Microsoft Visual Studio XAML design surface and select **Edit Style** or **Edit Template** (depending on the control you are right-clicking on). You can then apply an existing style by selecting **Apply Resource** or define a new style by selecting **Create Empty**. If you create an empty style, you are given the option to define it in the page, in the App.xaml file, or in a separate resource dictionary.

Lightweight styling

Overriding the system brushes is generally done at the App or Page level, and in either case the color override will affect all controls that reference that brush – and in XAML many controls can reference the same system brush.



XAML

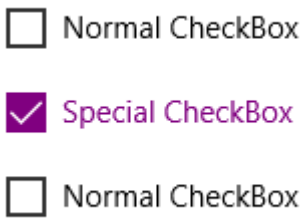
```
<Page.Resources>
    <ResourceDictionary>
        <ResourceDictionary.ThemeDictionaries>
            <ResourceDictionary x:Key="Light">
                <SolidColorBrush x:Key="ButtonBackground"
Color="Transparent"/>
                <SolidColorBrush x:Key="ButtonForeground"
Color="MediumSlateBlue"/>
                <SolidColorBrush x:Key="ButtonBorderBrush"
Color="MediumSlateBlue"/>
            </ResourceDictionary>
        </ResourceDictionary.ThemeDictionaries>
    </ResourceDictionary>
</Page.Resources>
```

For states like PointerOver (mouse is hovered over the button), **PointerPressed** (button has been invoked), or Disabled (button is not interactable). These endings are appended onto the original Lightweight styling names: **ButtonBackgroundPointerOver**, **ButtonForegroundPressed**, **ButtonBorderBrushDisabled**, etc. Modifying those brushes as well, will make sure that your controls are colored consistently to your app's theme.

Placing these brush overrides at the **App.Resources** level, will alter all the buttons within the entire app, instead of on a single page.

Per-control styling

In other cases, changing a single control on one page only to look a certain way, without altering any other versions of that control, is desired:



XAML

```
<CheckBox Content="Normal CheckBox" Margin="5"/>
<CheckBox Content="Special CheckBox" Margin="5">
    <CheckBox.Resources>
        <ResourceDictionary>
            <ResourceDictionary.ThemeDictionaries>
                <ResourceDictionary x:Key="Light">
                    <SolidColorBrush x:Key="CheckBoxForegroundUnchecked"
                        Color="Purple"/>
                    <SolidColorBrush x:Key="CheckBoxForegroundChecked"
                        Color="Purple"/>
                    <SolidColorBrush
x:Key="CheckBoxCheckGlyphForegroundChecked"
                        Color="White"/>
                    <SolidColorBrush
x:Key="CheckBoxCheckBackgroundStrokeChecked"
                        Color="Purple"/>
                    <SolidColorBrush
x:Key="CheckBoxCheckBackgroundFillChecked"
                        Color="Purple"/>
                </ResourceDictionary>
            </ResourceDictionary.ThemeDictionaries>
        </ResourceDictionary>
    </CheckBox.Resources>
</CheckBox>
<CheckBox Content="Normal CheckBox" Margin="5"/>
```

This would only effect that one "Special CheckBox" on the page where that control existed.

Custom controls

When you are building your own custom controls that may be visually and/or functionally aligned with our built-in controls, consider using implicit styling and Lightweight styling resources to define your custom content. You can either use the resources directly, or create a new alias for the resource.

Using control resources directly

For example, if you are writing a control that looks like a Button, you can have your control reference the button resources directly, like this:

XAML

```
<Style TargetType="local:MyCustomControl">
  <Setter Property="Background" Value="{ThemeResource ButtonBackground}" />
  <Setter Property="BorderBrush" Value="{ThemeResource ButtonBorderBrush}"
/>
</Style>
```

Aliasing control resources to new names

Alternatively, if you prefer to make your own resources, you should alias those custom names to our default Lightweight styling resources.

For example, your custom control's style might have special resource definitions:

XAML

```
<Style TargetType="local:MyCustomControl">
  <Setter Property="Background" Value="{ThemeResource
MyCustomControlBackground}" />
  <Setter Property="BorderBrush" Value="{ThemeResource
MyCustomControlBorderBrush}"/>
</Style>
```

In your Resource Dictionary or main definition, you would hook up the Lightweight styling resources to your custom ones:

XAML

```
<ResourceDictionary.ThemeDictionaries>
    <ResourceDictionary x:Key="Default">
        <StaticResource x:Key="MyCustomControlBackground"
ResourceKey="ButtonBackground" />
        <StaticResource x:Key="MyCustomControlBorderBrush"
ResourceKey="ButtonBorderBrush" />
    </ResourceDictionary>
    <ResourceDictionary x:Key="Light">
        <StaticResource x:Key="MyCustomControlBackground"
ResourceKey="ButtonBackground" />
        <StaticResource x:Key="MyCustomControlBorderBrush"
ResourceKey="ButtonBorderBrush" />
    </ResourceDictionary>
    <ResourceDictionary x:Key="HighContrast">
        <StaticResource x:Key="MyCustomControlBackground"
ResourceKey="ButtonBackground" />
```

```
        <StaticResource x:Key="MyCustomControlBorderBrush"
ResourceKey="ButtonBorderBrush" />
    </ResourceDictionary>
</ResourceDictionary.ThemeDictionaries>
```

Its required that you use a `ThemeDictionary` that is duplicated three times in order to handle the three different theme changes properly (`Default`, `Light`, `HighContrast`).

> **⊗ Caution**
>
> If you assign a Lightweight styling resource to a new alias, and also redefine the Lightweight styling resource, your customization might not be applied if the resource lookup is not in the correct order. For example, if you override `ButtonBackground` in a spot that is searched before `MyCustomControlBackground` is found, the override would be missed.

Avoid restyling controls

The WinUI 2.2 or later includes new styles and templates for both WinUI and system controls.

The best way to stay current with our latest visual styles is to use the latest WinUI 2 package and avoid custom styles and templates (also known as re-templating). Styles are still a convenient way to apply a set of values consistently across controls in your app. When doing this, make sure to be based on our latest styles.

For system controls that use WinUI styles (`Windows.UI.Xaml.Controls` namespace), set `BasedOn="{StaticResource Default<ControlName>Style}"`, where `<ControlName>` is the name of the control. For example:

XAML

```
<Style TargetType="TextBox" BasedOn="{StaticResource DefaultTextBoxStyle}">
    <Setter Property="Foreground" Value="Blue"/>
</Style>
```

For WinUI 2 controls (`Microsoft.UI.Xaml.Controls` namespace), the default style is defined in the metadata, so omit `BasedOn`.

Derived controls

If you derive a custom control from an existing XAML control, it will not get the WinUI 2 styles by default. To apply the WinUI 2 styles:

- Create a new Style with its TargetType set to your custom control.
- Base the Style on the default style of the control you derived from.

One common scenario for this is to derive a new control from ContentDialog. This example shows how to create a new Style that applies `DefaultContentDialogStyle` to your custom dialog.

XAML

```
<ContentDialog
    x:Class="ExampleApp.SignInContentDialog"
    ... >

    <ContentDialog.Resources>
        <Style TargetType="local:SignInContentDialog" BasedOn="
{StaticResource DefaultContentDialogStyle}"/>
        ...
    </ContentDialog.Resources>
    <!-- CONTENT -->
</ContentDialog>
```

The template property

A style setter can be used for the Template property of a Control, and in fact this makes up the majority of a typical XAML style and an app's XAML resources. This is discussed in more detail in the topic Control templates.

Control templates

Article • 11/26/2024

You can customize a control's visual structure and visual behavior by creating a control template in the XAML framework. Controls have many properties, such as **Background**, **Foreground**, and **FontFamily**, that you can set to specify different aspects of the control's appearance. But the changes that you can make by setting these properties are limited. You can specify additional customizations by creating a template using the **ControlTemplate** class. Here, we show you how to create a **ControlTemplate** to customize the appearance of a **CheckBox** control.

> **Important APIs**: **ControlTemplate class**, **Control.Template property**

Custom control template example

By default, a **CheckBox** control puts its content (the string or object next to the **CheckBox**) to the right of the selection box, and a check mark indicates that a user selected the **CheckBox**. These characteristics represent the visual structure and visual behavior of the **CheckBox**.

Here's a **CheckBox** using the default **ControlTemplate** shown in the `Unchecked`, `Checked`, and `Indeterminate` states.

You can change these characteristics by creating a **ControlTemplate** for the **CheckBox**. For example, if you want the content of the check box to be below the selection box, and you want to use an **X** to indicate that a user selected the check box. You specify these characteristics in the **ControlTemplate** of the **CheckBox**.

To use a custom template with a control, assign the **ControlTemplate** to the **Template** property of the control. Here's a **CheckBox** using a **ControlTemplate** called `CheckBoxTemplate1`. We show the Extensible Application Markup Language (XAML) for the **ControlTemplate** in the next section.

```
XAML
```

```
<CheckBox Content="CheckBox" Template="{StaticResource CheckBoxTemplate1}"
IsThreeState="True" Margin="20"/>
```

Here's how this **CheckBox** looks in the `Unchecked`, `Checked`, and `Indeterminate` states after we apply our template.

Specify the visual structure of a control

When you create a **ControlTemplate**, you combine **FrameworkElement** objects to build a single control. A **ControlTemplate** must have only one **FrameworkElement** as its root element. The root element usually contains other **FrameworkElement** objects. The combination of objects makes up the control's visual structure.

This XAML creates a **ControlTemplate** for a **CheckBox** that specifies that the content of the control is below the selection box. The root element is a **Border**. The example specifies a **Path** to create an **X** that indicates that a user selected the **CheckBox**, and an **Ellipse** that indicates an indeterminate state. Note that the **Opacity** is set to 0 on the **Path** and the **Ellipse** so that by default, neither appear.

A TemplateBinding is a special binding that links the value of a property in a control template to the value of some other exposed property on the templated control. TemplateBinding can only be used within a ControlTemplate definition in XAML. See TemplateBinding markup extension for more info.

> **Note**
>
> Starting with Windows 10, version 1809 (SDK 17763), you can use x:Bind markup extensions in places you use TemplateBinding. See TemplateBinding markup extension for more info.

XAML

```
<ControlTemplate x:Key="CheckBoxTemplate1" TargetType="CheckBox">
    <Border BorderBrush="{TemplateBinding BorderBrush}"
            BorderThickness="{TemplateBinding BorderThickness}"
```

```
            Background="{TemplateBinding Background}">
        <Grid>
            <Grid.RowDefinitions>
                <RowDefinition Height="*"/>
                <RowDefinition Height="25"/>
            </Grid.RowDefinitions>
            <Rectangle x:Name="NormalRectangle" Fill="Transparent"
Height="20" Width="20"
                       Stroke="{ThemeResource
SystemControlForegroundBaseMediumHighBrush}"
                       StrokeThickness="{ThemeResource
CheckBoxBorderThemeThickness}"
                       UseLayoutRounding="False"/>
            <!-- Create an X to indicate that the CheckBox is selected. -->
            <Path x:Name="CheckGlyph"
                  Data="M103,240 L111,240 119,248 127,240 135,240 123,252
135,264 127,264 119,257 111,264 103,264 114,252 z"
                  Fill="{ThemeResource CheckBoxForegroundThemeBrush}"
                  FlowDirection="LeftToRight"
                  Height="14" Width="16" Opacity="0" Stretch="Fill"/>
            <Ellipse x:Name="IndeterminateGlyph"
                     Fill="{ThemeResource CheckBoxForegroundThemeBrush}"
                     Height="8" Width="8" Opacity="0"
UseLayoutRounding="False" />
            <ContentPresenter x:Name="ContentPresenter"
                              ContentTemplate="{TemplateBinding
ContentTemplate}"
                              Content="{TemplateBinding Content}"
                              Margin="{TemplateBinding Padding}"
Grid.Row="1"
                              HorizontalAlignment="Center"
                              VerticalAlignment="{TemplateBinding
VerticalContentAlignment}"/>
        </Grid>
    </Border>
</ControlTemplate>
```

Specify the visual behavior of a control

A visual behavior specifies the appearance of a control when it is in a certain state. The **CheckBox** control has 3 check states: `Checked`, `Unchecked`, and `Indeterminate`. The value of the **IsChecked** property determines the state of the **CheckBox**, and its state determines what appears in the box.

This table lists the possible values of **IsChecked**, the corresponding states of the **CheckBox**, and the appearance of the **CheckBox**.

Expand table

IsChecked value	CheckBox state	CheckBox appearance
true	`Checked`	Contains an "X".
false	`Unchecked`	Empty.
null	`Indeterminate`	Contains a circle.

You specify the appearance of a control when it is in a certain state by using VisualState objects. A **VisualState** contains a Setter or Storyboard that changes the appearance of the elements in the ControlTemplate. When the control enters the state that the VisualState.Name property specifies, the property changes in the **Setter** or Storyboard are applied. When the control exits the state, the changes are removed. You add **VisualState** objects to VisualStateGroup objects. You add **VisualStateGroup** objects to the VisualStateManager.VisualStateGroups attached property, which you set on the root FrameworkElement of the **ControlTemplate**.

This XAML shows the VisualState objects for the `Checked`, `Unchecked`, and `Indeterminate` states. The example sets the VisualStateManager.VisualStateGroups attached property on the Border, which is the root element of the ControlTemplate. The `Checked` **VisualState** specifies that the Opacity of the Path named `CheckGlyph` (which we show in the previous example) is 1. The `Indeterminate` **VisualState** specifies that the **Opacity** of the Ellipse named `IndeterminateGlyph` is 1. The `Unchecked` **VisualState** has no Setter or Storyboard, so the CheckBox returns to its default appearance.

XAML

```
<ControlTemplate x:Key="CheckBoxTemplate1" TargetType="CheckBox">
    <Border BorderBrush="{TemplateBinding BorderBrush}"
            BorderThickness="{TemplateBinding BorderThickness}"
            Background="{TemplateBinding Background}">

        <VisualStateManager.VisualStateGroups>
            <VisualStateGroup x:Name="CheckStates">
                <VisualState x:Name="Checked">
                    <VisualState.Setters>
                        <Setter Target="CheckGlyph.Opacity" Value="1"/>
                    </VisualState.Setters>
                    <!-- This Storyboard is equivalent to the Setter. -->
                    <!--<Storyboard>
                        <DoubleAnimation Duration="0" To="1"
                         Storyboard.TargetName="CheckGlyph"
Storyboard.TargetProperty="Opacity"/>
                    </Storyboard>-->
                </VisualState>
                <VisualState x:Name="Unchecked"/>
                <VisualState x:Name="Indeterminate">
                    <VisualState.Setters>
```

```
                        <Setter Target="IndeterminateGlyph.Opacity"
Value="1"/>
                    </VisualState.Setters>
                    <!-- This Storyboard is equivalent to the Setter. -->
                    <!--<Storyboard>
                        <DoubleAnimation Duration="0" To="1"
                         Storyboard.TargetName="IndeterminateGlyph"
Storyboard.TargetProperty="Opacity"/>
                    </Storyboard>-->
                </VisualState>
            </VisualStateGroup>
        </VisualStateManager.VisualStateGroups>

        <Grid>
            <Grid.RowDefinitions>
                <RowDefinition Height="*"/>
                <RowDefinition Height="25"/>
            </Grid.RowDefinitions>
            <Rectangle x:Name="NormalRectangle" Fill="Transparent"
Height="20" Width="20"
                       Stroke="{ThemeResource
SystemControlForegroundBaseMediumHighBrush}"
                       StrokeThickness="{ThemeResource
CheckBoxBorderThemeThickness}"
                       UseLayoutRounding="False"/>
            <!-- Create an X to indicate that the CheckBox is selected. -->
            <Path x:Name="CheckGlyph"
                  Data="M103,240 L111,240 119,248 127,240 135,240 123,252
135,264 127,264 119,257 111,264 103,264 114,252 z"
                  Fill="{ThemeResource CheckBoxForegroundThemeBrush}"
                  FlowDirection="LeftToRight"
                  Height="14" Width="16" Opacity="0" Stretch="Fill"/>
            <Ellipse x:Name="IndeterminateGlyph"
                     Fill="{ThemeResource CheckBoxForegroundThemeBrush}"
                     Height="8" Width="8" Opacity="0"
UseLayoutRounding="False" />
            <ContentPresenter x:Name="ContentPresenter"
                              ContentTemplate="{TemplateBinding
ContentTemplate}"
                              Content="{TemplateBinding Content}"
                              Margin="{TemplateBinding Padding}"
Grid.Row="1"
                              HorizontalAlignment="Center"
                              VerticalAlignment="{TemplateBinding
VerticalContentAlignment}"/>
        </Grid>
    </Border>
</ControlTemplate>
```

To better understand how **VisualState** objects work, consider what happens when the **CheckBox** goes from the `Unchecked` state to the `Checked` state, then to the `Indeterminate` state, and then back to the `Unchecked` state. Here are the transitions.

Expand table

State transition	What happens	CheckBox appearance when the transition completes
From `Unchecked` to `Checked`.	The **Setter** value of the `Checked` **VisualState** is applied, so the **Opacity** of `CheckGlyph` is 1.	An X is displayed.
From `Checked` to `Indeterminate`.	The **Setter** value of the `Indeterminate` **VisualState** is applied, so the **Opacity** of `IndeterminateGlyph` is 1. The **Setter** value of the `Checked` **VisualState** is removed, so the **Opacity** of `CheckGlyph` is 0.	A circle is displayed.
From `Indeterminate` to `Unchecked`.	The **Setter** value of the `Indeterminate` **VisualState** is removed, so the **Opacity** of `IndeterminateGlyph` is 0.	Nothing is displayed.

For more info about how to create visual states for controls, and in particular how to use the **Storyboard** class and the animation types, see Storyboarded animations for visual states.

Use tools to work with themes easily

A fast way to apply themes to your controls is to right-click on a control on the Microsoft Visual Studio **Document Outline** and select **Edit Theme** or **Edit Style** (depending on the control you are right-clicking on). You can then apply an existing theme by selecting **Apply Resource** or define a new one by selecting **Create Empty**.

Controls and accessibility

When you create a new template for a control, in addition to possibly changing the control's behavior and visual appearance, you might also be changing how the control represents itself to accessibility frameworks. The Windows app supports the Microsoft UI Automation framework for accessibility. All of the default controls and their templates have support for common UI Automation control types and patterns that are appropriate for the control's purpose and function. These control types and patterns are interpreted by UI Automation clients such as assistive technologies, and this enables a control to be accessible as a part of a larger accessible app UI.

To separate the basic control logic and also to satisfy some of the architectural requirements of UI Automation, control classes include their accessibility support in a

separate class, an automation peer. The automation peers sometimes have interactions with the control templates because the peers expect certain named parts to exist in the templates, so that functionality such as enabling assistive technologies to invoke actions of buttons is possible.

When you create a completely new custom control, you sometimes also will want to create a new automation peer to go along with it. For more info, see Custom automation peers.

Learn more about a control's default template

The topics that document the styles and templates for XAML controls show you excerpts of the same starting XAML you'd see if you used the **Edit Theme** or **Edit Style** techniques explained previously. Each topic lists the names of the visual states, the theme resources used, and the full XAML for the style that contains the template. The topics can be useful guidance if you've already started modifying a template and want to see what the original template looked like, or to verify that your new template has all of the required named visual states.

Theme resources in control templates

For some of the attributes in the XAML examples, you may have noticed resource references that use the {ThemeResource} markup extension. This is a technique that enables a single control template to use resources that can be different values depending on which theme is currently active. This is particularly important for brushes and colors, because the main purpose of the themes is to enable users to choose whether they want a dark, light, or high contrast theme applied to the system overall. Apps that use the XAML resource system can use a resource set that's appropriate for that theme, so that the theme choices in an app's UI are reflective of the user's systemwide theme choice.

ResourceDictionary and XAML resource references

Article • 11/26/2024

You can define the UI or resources for your app using XAML. Resources are typically definitions of some object that you expect to use more than once. To refer to a XAML resource later, you specify a key for a resource that acts like its name. You can reference a resource throughout an app or from any XAML page within it. You can define your resources using a ResourceDictionary element from the Windows Runtime XAML. Then, you can reference your resources by using a StaticResource markup extension or ThemeResource markup extension.

The XAML elements you might want to declare most often as XAML resources include Style, ControlTemplate, animation components, and Brush subclasses. Here, we explain how to define a ResourceDictionary and keyed resources, and how XAML resources relate to other resources that you define as part of your app or app package. We also explain resource dictionary advanced features such as MergedDictionaries and ThemeDictionaries.

Prerequisites

A solid understanding of XAML markup. We recommend reading XAML overview.

Define and use XAML resources

XAML resources are objects that are referenced from markup more than once. Resources are defined in a ResourceDictionary, typically in a separate file or at the top of the markup page, like this.

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">

    <Page.Resources>
        <x:String x:Key="greeting">Hello world</x:String>
        <x:String x:Key="goodbye">Goodbye world</x:String>
    </Page.Resources>

    <TextBlock Text="{StaticResource greeting}" Foreground="Gray"
```

```
VerticalAlignment="Center"/>
</Page>
```

In this example:

- `<Page.Resources>…</Page.Resources>` - Defines the resource dictionary.
- `<x:String>` - Defines the resource with the key "greeting".
- `{StaticResource greeting}` - Looks up the resource with the key "greeting", which is assigned to the Text property of the TextBlock.

> **Note** Don't confuse the concepts related to ResourceDictionary with the **Resource** build action, resource (.resw) files, or other "resources" that are discussed in the context of structuring the code project that produces your app package.

Resources don't have to be strings; they can be any shareable object, such as styles, templates, brushes, and colors. However, controls, shapes, and other FrameworkElements are not shareable, so they can't be declared as reusable resources. For more info about sharing, see the XAML resources must be shareable section later in this topic.

Here, both a brush and a string are declared as resources and used by controls in a page.

XAML

```
<Page
    x:Class="SpiderMSDN.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">

    <Page.Resources>
        <SolidColorBrush x:Key="myFavoriteColor" Color="green"/>
        <x:String x:Key="greeting">Hello world</x:String>
    </Page.Resources>

    <TextBlock Foreground="{StaticResource myFavoriteColor}" Text="
{StaticResource greeting}" VerticalAlignment="Top"/>
    <Button Foreground="{StaticResource myFavoriteColor}" Content="
{StaticResource greeting}" VerticalAlignment="Center"/>
</Page>
```

All resources need to have a key. Usually that key is a string defined with `x:Key="myString"`. However, there are a few other ways to specify a key:

- Style and ControlTemplate require a **TargetType**, and will use the **TargetType** as the key if x:Key is not specified. In this case, the key is the actual Type object, not a

string. (See examples below)

- DataTemplate resources that have a **TargetType** will use the **TargetType** as the key if x:Key is not specified. In this case, the key is the actual Type object, not a string.
- x:Name can be used instead of x:Key. However, x:Name also generates a code behind field for the resource. As a result, x:Name is less efficient than x:Key because that field needs to be initialized when the page is loaded.

The StaticResource markup extension can retrieve resources only with a string name (x:Key or x:Name). However, the XAML framework also looks for implicit style resources (those which use **TargetType** rather than x:Key or x:Name) when it decides which style & template to use for a control that hasn't set the Style and ContentTemplate or ItemTemplate properties.

Here, the Style has an implicit key of **typeof(Button)**, and since the Button at the bottom of the page doesn't specify a Style property, it looks for a style with key of **typeof(Button)**:

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">

    <Page.Resources>
        <Style TargetType="Button">
            <Setter Property="Background" Value="Red"/>
        </Style>
    </Page.Resources>
    <Grid>
       <!-- This button will have a red background. -->
       <Button Content="Button" Height="100" VerticalAlignment="Center"
Width="100"/>
    </Grid>
</Page>
```

For more info about implicit styles and how they work, see Styling controls and Control templates.

Look up resources in code

You access members of the resource dictionary like any other dictionary.

> ⚠ **Warning**

When you perform a resource lookup in code, only the resources in the `Page.Resources` dictionary are looked at. Unlike the StaticResource markup extension, the code doesn't fall back to the `Application.Resources` dictionary if the resources aren't found in the first dictionary.

This example shows how to retrieve the `redButtonStyle` resource out of a page's resource dictionary:

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">

    <Page.Resources>
        <Style TargetType="Button" x:Key="redButtonStyle">
            <Setter Property="Background" Value="red"/>
        </Style>
    </Page.Resources>
</Page>
```

C#

```
    public sealed partial class MainPage : Page
    {
        public MainPage()
        {
            this.InitializeComponent();
            Style redButtonStyle = (Style)this.Resources["redButtonStyle"];
        }
    }
```

To look up app-wide resources from code, use **Application.Current.Resources** to get the app's resource dictionary, as shown here.

XAML

```
<Application
    x:Class="MSDNSample.App"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:SpiderMSDN">
    <Application.Resources>
        <Style TargetType="Button" x:Key="appButtonStyle">
            <Setter Property="Background" Value="red"/>
```

```
        </Style>
    </Application.Resources>

</Application>
```

C#

```
    public sealed partial class MainPage : Page
    {
        public MainPage()
        {
            this.InitializeComponent();
            Style appButtonStyle =
(Style)Application.Current.Resources["appButtonStyle"];
        }
    }
```

You can also add an application resource in code.

There are two things to keep in mind when doing this.

- First, you need to add the resources before any page tries to use the resource.
- Second, you can't add resources in the App's constructor.

You can avoid both problems if you add the resource in the Application.OnLaunched method, like this.

C#

```
// App.xaml.cs

sealed partial class App : Application
{
    protected override void OnLaunched(LaunchActivatedEventArgs e)
    {
        Frame rootFrame = Window.Current.Content as Frame;
        if (rootFrame == null)
        {
            SolidColorBrush brush = new
SolidColorBrush(Windows.UI.Color.FromArgb(255, 0, 255, 0)); // green
            this.Resources["brush"] = brush;
            // … Other code that VS generates for you …
        }
    }
}
```

Every FrameworkElement can have a ResourceDictionary

FrameworkElement is a base class that controls inherit from, and it has a Resources property. So, you can add a local resource dictionary to any **FrameworkElement**.

Here, both the Page and the Border have resource dictionaries, and they both have a resource called "greeting". The TextBlock named 'textBlock2' is inside the **Border**, so its resource lookup looks first to the **Border**'s resources, then the **Page**'s resources, and then the Application resources. The **TextBlock** will read "Hola mundo".

To access that element's resources from code, use that element's Resources property. Accessing a FrameworkElement's resources in code, rather than XAML, will look only in that dictionary, not in parent element's dictionaries.

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">
    <Page.Resources>
        <x:String x:Key="greeting">Hello world</x:String>
    </Page.Resources>

    <StackPanel>
        <!-- Displays "Hello world" -->
        <TextBlock x:Name="textBlock1" Text="{StaticResource greeting}"/>

        <Border x:Name="border">
            <Border.Resources>
                <x:String x:Key="greeting">Hola mundo</x:String>
            </Border.Resources>
            <!-- Displays "Hola mundo" -->
            <TextBlock x:Name="textBlock2" Text="{StaticResource
greeting}"/>
        </Border>

        <!-- Displays "Hola mundo", set in code. -->
        <TextBlock x:Name="textBlock3"/>
    </StackPanel>
</Page>
```

C#

```
    public sealed partial class MainPage : Page
    {
```

```
        public MainPage()
        {
            this.InitializeComponent();
            textBlock3.Text = (string)border.Resources["greeting"];
        }
    }
```

Merged resource dictionaries

A *merged resource dictionary* combines one resource dictionary into another, usually in another file.

> **Tip** You can create a resource dictionary file in Microsoft Visual Studio by using the **Add** > **New Item...** > **Resource Dictionary** option from the **Project** menu.

Here, you define a resource dictionary in a separate XAML file called Dictionary1.xaml.

XAML

```
<!-- Dictionary1.xaml -->
<ResourceDictionary
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:MSDNSample">

    <SolidColorBrush x:Key="brush" Color="Red"/>

</ResourceDictionary>
```

To use that dictionary, you merge it with your page's dictionary:

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">
    <Page.Resources>
        <ResourceDictionary>
            <ResourceDictionary.MergedDictionaries>
                <ResourceDictionary Source="Dictionary1.xaml"/>
            </ResourceDictionary.MergedDictionaries>

            <x:String x:Key="greeting">Hello world</x:String>

        </ResourceDictionary>
    </Page.Resources>
```

```
    <TextBlock Foreground="{StaticResource brush}" Text="{StaticResource
greeting}" VerticalAlignment="Center"/>
</Page>
```

Here's what happens in this example. In `<Page.Resources>`, you declare `<ResourceDictionary>`. The XAML framework implicitly creates a resource dictionary for you when you add resources to `<Page.Resources>`; however, in this case, you don't want just any resource dictionary, you want one that contains merged dictionaries.

So you declare `<ResourceDictionary>`, then add things to its `<ResourceDictionary.MergedDictionaries>` collection. Each of those entries takes the form `<ResourceDictionary Source="Dictionary1.xaml"/>`. To add more than one dictionary, just add a `<ResourceDictionary Source="Dictionary2.xaml"/>` entry after the first entry.

After `<ResourceDictionary.MergedDictionaries>…</ResourceDictionary.MergedDictionaries>`, you can optionally put additional resources in your main dictionary. You use resources from a merged to dictionary just like a regular dictionary. In the example above, `{StaticResource brush}` finds the resource in the child/merged dictionary (Dictionary1.xaml), while `{StaticResource greeting}` finds its resource in the main page dictionary.

In the resource-lookup sequence, a MergedDictionaries dictionary is checked only after a check of all the other keyed resources of that ResourceDictionary. After searching that level, the lookup reaches the merged dictionaries, and each item in **MergedDictionaries** is checked. If multiple merged dictionaries exist, these dictionaries are checked in the inverse of the order in which they are declared in the **MergedDictionaries** property. In the following example, if both Dictionary2.xaml and Dictionary1.xaml declared the same key, the key from Dictionary2.xaml is used first because it's last in the **MergedDictionaries** set.

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">
    <Page.Resources>
        <ResourceDictionary>
            <ResourceDictionary.MergedDictionaries>
                <ResourceDictionary Source="Dictionary1.xaml"/>
                <ResourceDictionary Source="Dictionary2.xaml"/>
            </ResourceDictionary.MergedDictionaries>
        </ResourceDictionary>
```

```
    </Page.Resources>

    <TextBlock Foreground="{StaticResource brush}" Text="greetings!"
VerticalAlignment="Center"/>
</Page>
```

Within the scope of any one ResourceDictionary, the dictionary is checked for key uniqueness. However, that scope does not extend across different items in different MergedDictionaries files.

You can use the combination of the lookup sequence and lack of unique key enforcement across merged-dictionary scopes to create a fallback value sequence of ResourceDictionary resources. For example, you might store user preferences for a particular brush color in the last merged resource dictionary in the sequence, using a resource dictionary that synchronizes to your app's state and user preference data. However, if no user preferences exist yet, you can define that same key string for a **ResourceDictionary** resource in the initial MergedDictionaries file, and it can serve as the fallback value. Remember that any value you provide in a primary resource dictionary is always checked before the merged dictionaries are checked, so if you want to use the fallback technique, don't define that resource in a primary resource dictionary.

Theme resources and theme dictionaries

A ThemeResource is similar to a StaticResource, but the resource lookup is reevaluated when the theme changes.

In this example, you set the foreground of a TextBlock to a value from the current theme.

XAML

```
<TextBlock Text="hello world" Foreground="{ThemeResource
FocusVisualWhiteStrokeThemeBrush}" VerticalAlignment="Center"/>
```

A theme dictionary is a special type of merged dictionary that holds the resources that vary with the theme a user is currently using on his or her device. For example, the "light" theme might use a white color brush whereas the "dark" theme might use a dark color brush. The brush changes the resource that it resolves to, but otherwise the composition of a control that uses the brush as a resource could be the same. To reproduce the theme-switching behavior in your own templates and styles, instead of using MergedDictionaries as the property to merge items into the main dictionaries, use the ThemeDictionaries property.

Each ResourceDictionary element within ThemeDictionaries must have an x:Key value. The value is a string that names the relevant theme—for example, "Default", "Dark", "Light", or "HighContrast". Typically, `Dictionary1` and `Dictionary2` will define resources that have the same names but different values.

Here, you use red text for the light theme and blue text for the dark theme.

XAML

```
<!-- Dictionary1.xaml -->
<ResourceDictionary
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:MSDNSample">

    <SolidColorBrush x:Key="brush" Color="Red"/>

</ResourceDictionary>

<!-- Dictionary2.xaml -->
<ResourceDictionary
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml"
    xmlns:local="using:MSDNSample">

    <SolidColorBrush x:Key="brush" Color="blue"/>

</ResourceDictionary>
```

In this example, you set the foreground of a TextBlock to a value from the current theme.

XAML

```
<Page
    x:Class="MSDNSample.MainPage"
    xmlns="http://schemas.microsoft.com/winfx/2006/xaml/presentation"
    xmlns:x="http://schemas.microsoft.com/winfx/2006/xaml">
    <Page.Resources>
        <ResourceDictionary>
            <ResourceDictionary.ThemeDictionaries>
                <ResourceDictionary Source="Dictionary1.xaml"
x:Key="Light"/>
                <ResourceDictionary Source="Dictionary2.xaml" x:Key="Dark"/>
            </ResourceDictionary.ThemeDictionaries>
        </ResourceDictionary>
    </Page.Resources>
    <TextBlock Foreground="{StaticResource brush}" Text="hello world"
VerticalAlignment="Center"/>
</Page>
```

For theme dictionaries, the active dictionary to be used for resource lookup changes dynamically, whenever ThemeResource markup extension is used to make the reference and the system detects a theme change. The lookup behavior that is done by the system is based on mapping the active theme to the x:Key of a specific theme dictionary.

It can be useful to examine the way that the theme dictionaries are structured in the default XAML design resources, which parallel the templates that the Windows Runtime uses by default for its controls. Open the XAML files in \(Program Files)\Windows Kits\10\DesignTime\CommonConfiguration\Neutral\UAP\<SDK version>\Generic using a text editor or your IDE. Note how the theme dictionaries are defined first in generic.xaml, and how each theme dictionary defines the same keys. Each such key is then referenced by elements of composition in the various keyed elements that are outside the theme dictionaries and defined later in the XAML. There's also a separate themeresources.xaml file for design that contains only the theme resources and extra templates, not the default control templates. The theme areas are duplicates of what you'd see in generic.xaml.

When you use XAML design tools to edit copies of styles and templates, the design tools extract sections from the XAML design resource dictionaries and place them as local copies of XAML dictionary elements that are part of your app and project.

For more info and for a list of the theme-specific and system resources that are available to your app, see XAML theme resources.

Lookup behavior for XAML resource references

Lookup behavior is the term that describes how the XAML resources system tries to find a XAML resource. The lookup occurs when a key is referenced as a XAML resource reference from somewhere in the app's XAML. First, the resources system has predictable behavior for where it will check for the existence of a resource based on scope. If a resource isn't found in the initial scope, the scope expands. The lookup behavior continues on throughout the locations and scopes that a XAML resource could possibly be defined by an app or by the system. If all possible resource lookup attempts fail, an error often results. It's usually possible to eliminate these errors during the development process.

The lookup behavior for XAML resource references starts with the object where the actual usage is applied and its own Resources property. If a ResourceDictionary exists there, that **ResourceDictionary** is checked for an item that has the requested key. This first level of lookup is rarely relevant because you usually do not define and then reference a resource on the same object. In fact, a **Resources** property often doesn't

exist here. You can make XAML resource references from nearly anywhere in XAML; you aren't limited to properties of FrameworkElement subclasses.

The lookup sequence then checks the next parent object in the runtime object tree of the app. If a FrameworkElement.Resources exists and holds a ResourceDictionary, the dictionary item with the specified key string is requested. If the resource is found, the lookup sequence stops and the object is provided to the location where the reference was made. Otherwise, the lookup behavior advances to the next parent level towards the object tree root. The search continues recursively upwards until the root element of the XAML is reached, exhausting the search of all possible immediate resource locations.

> **Note**
>
> It is a common practice to define all the immediate resources at the root level of a page, both to take advantage of this resource-lookup behavior and also as a convention of XAML markup style.

If the requested resource is not found in the immediate resources, the next lookup step is to check the Application.Resources property. **Application.Resources** is the best place to put any app-specific resources that are referenced by multiple pages in your app's navigation structure.

> **Important**
>
> The order of resources added to a ResourceDictionary affects the order in which they are applied. The `XamlControlsResources` dictionary overrides many default resource keys and should therefore be added to `Application.Resources` first so that it doesn't override any other custom styles or resources in your app.

Control templates have another possible location in the reference lookup: theme dictionaries. A theme dictionary is a single XAML file that has a ResourceDictionary element as its root. The theme dictionary might be a merged dictionary from Application.Resources. The theme dictionary might also be the control-specific theme dictionary for a templated custom control.

Finally, there is a resource lookup against platform resources. Platform resources include the control templates that are defined for each of the system UI themes, and which define the default appearance of all the controls that you use for UI in a Windows Runtime app. Platform resources also include a set of named resources that relate to system-wide appearance and themes. These resources are technically a MergedDictionaries item, and thus are available for lookup from XAML or code once the

app has loaded. For example, the system theme resources include a resource named "SystemColorWindowTextColor" that provides a Color definition to match app text color to a system window's text color that comes from the operating system and user preferences. Other XAML styles for your app can refer to this style, or your code can get a resource lookup value (and cast it to **Color** in the example case).

For more info and for a list of the theme-specific and system resources that are available to a Windows app that uses XAML, see XAML theme resources.

If the requested key is still not found in any of these locations, a XAML parsing error/exception occurs. In certain circumstances, the XAML parse exception may be a run-time exception that is not detected either by a XAML markup compile action, or by a XAML design environment.

Because of the tiered lookup behavior for resource dictionaries, you can deliberately define multiple resource items that each have the same string value as the key, as long as each resource is defined at a different level. In other words, although keys must be unique within any given ResourceDictionary, the uniqueness requirement does not extend to the lookup behavior sequence as a whole. During lookup, only the first such object that's successfully retrieved is used for the XAML resource reference, and then the lookup stops. You could use this behavior to request the same XAML resource by key at various positions within your app's XAML but get different resources back, depending on the scope from which the XAML resource reference was made and how that particular lookup behaves.

Forward references within a ResourceDictionary

XAML resource references within a particular resource dictionary must reference a resource that has already been defined with a key, and that resource must appear lexically before the resource reference. Forward references cannot be resolved by a XAML resource reference. For this reason, if you use XAML resource references from within another resource, you must design your resource dictionary structure so that the resources that are used by other resources are defined first in a resource dictionary.

Resources defined at the app level cannot make references to immediate resources. This is equivalent to attempting a forward reference, because the app resources are actually processed first (when the app first starts, and before any navigation-page content is loaded). However, any immediate resource can make a reference to an app resource, and this can be a useful technique for avoiding forward-reference situations.

XAML resources must be shareable

For an object to exist in a ResourceDictionary, that object must be *shareable*.

Being shareable is required because, when the object tree of an app is constructed and used at run time, objects cannot exist at multiple locations in the tree. Internally, the resource system creates copies of resource values to use in the object graph of your app when each XAML resource is requested.

A ResourceDictionary and Windows Runtime XAML in general supports these objects for shareable usage:

- Styles and templates (Style and classes derived from FrameworkTemplate)
- Brushes and colors (classes derived from Brush, and Color values)
- Animation types including Storyboard
- Transforms (classes derived from GeneralTransform)
- Matrix and Matrix3D
- Point values
- Certain other UI-related structures such as Thickness and CornerRadius
- XAML intrinsic data types

You can also use custom types as a shareable resource if you follow the necessary implementation patterns. You define such classes in your backing code (or in runtime components that you include) and then instantiate those classes in XAML as a resource. Examples are object data sources and IValueConverter implementations for data binding.

Custom types must have a default constructor, because that's what a XAML parser uses to instantiate a class. Custom types used as resources can't have the UIElement class in their inheritance, because a **UIElement** can never be shareable (it's always intended to represent exactly one UI element that exists at one position in the object graph of your runtime app).

UserControl usage scope

A UserControl element has a special situation for resource-lookup behavior because it has the inherent concepts of a definition scope and a usage scope. A **UserControl** that makes a XAML resource reference from its definition scope must be able to support the lookup of that resource within its own definition-scope lookup sequence—that is, it cannot access app resources. From a **UserControl** usage scope, a resource reference is treated as being within the lookup sequence towards its usage page root (just like any

other resource reference made from an object in a loaded object tree) and can access app resources.

ResourceDictionary and XamlReader.Load

You can use a ResourceDictionary as either the root or a part of the XAML input for the XamlReader.Load method. You can also include XAML resource references in that XAML if all such references are completely self-contained in the XAML submitted for loading. **XamlReader.Load** parses the XAML in a context that is not aware of any other **ResourceDictionary** objects, not even Application.Resources. Also, don't use `{ThemeResource}` from within XAML submitted to **XamlReader.Load**.

Using a ResourceDictionary from code

Most of the scenarios for a ResourceDictionary are handled exclusively in XAML. You declare the **ResourceDictionary** container and the resources within as a XAML file or set of XAML nodes in a UI definition file. And then you use XAML resource references to request those resources from other parts of XAML. Still, there are certain scenarios where your app might want to adjust the contents of a **ResourceDictionary** using code that executes while the app is running, or at least to query the contents of a **ResourceDictionary** to see if a resource is already defined. These code calls are made on a **ResourceDictionary** instance, so you must first retrieve one—either an immediate **ResourceDictionary** somewhere in the object tree by getting FrameworkElement.Resources, or `Application.Current.Resources`.

In C# or Microsoft Visual Basic code, you can reference a resource in a given ResourceDictionary by using the indexer (Item). A **ResourceDictionary** is a string-keyed dictionary, so the indexer uses the string key instead of an integer index. In Visual C++ component extensions (C++/CX) code, use Lookup.

When using code to examine or change a ResourceDictionary, the behavior for APIs like Lookup or Item does not traverse from immediate resources to app resources; that's a XAML parser behavior that only happens as XAML pages are loaded. At run time, scope for keys is self-contained to the **ResourceDictionary** instance that you are using at the time. However, that scope does extend into MergedDictionaries.

Also, if you request a key that does not exist in the ResourceDictionary, there may not be an error; the return value may simply be provided as **null**. You may still get an error, though, if you try to use the returned **null** as a value. The error would come from the property's setter, not your **ResourceDictionary** call. The only way you'd avoid an error is if the property accepted **null** as a valid value. Note how this behavior contrasts with

XAML lookup behavior at XAML parse time; a failure to resolve the provided key from XAML at parse time results in a XAML parse error, even in cases where the property could have accepted **null**.

Merged resource dictionaries are included into the index scope of the primary resource dictionary that references the merged dictionary at run time. In other words, you can use **Item** or Lookup of the primary dictionary to find any objects that were actually defined in the merged dictionary. In this case, the lookup behavior does resemble the parse-time XAML lookup behavior: if there are multiple objects in merged dictionaries that each have the same key, the object from the last-added dictionary is returned.

You are permitted to add items to an existing ResourceDictionary by calling **Add** (C# or Visual Basic) or Insert (C++/CX). You could add the items to either immediate resources or app resources. Either of these API calls requires a key, which satisfies the requirement that each item in a **ResourceDictionary** must have a key. However, items that you add to a **ResourceDictionary** at run time are not relevant to XAML resource references. The necessary lookup for XAML resource references happens when that XAML is first parsed as the app is loaded (or a theme change is detected). Resources added to collections at run time weren't available then, and altering the **ResourceDictionary** doesn't invalidate an already retrieved resource from it even if you change the value of that resource.

You also can remove items from a ResourceDictionary at run time, make copies of some or all items, or other operations. The members listing for **ResourceDictionary** indicates which APIs are available. Note that because **ResourceDictionary** has a projected API to support its underlying collection interfaces, your API options differ depending on whether you are using C# or Visual Basic versus C++/CX.

ResourceDictionary and localization

A XAML ResourceDictionary might initially contain strings that are to be localized. If so, store these strings as project resources instead of in a **ResourceDictionary**. Take the strings out of the XAML, and instead give the owning element an x:Uid directive value. Then, define a resource in a resources file. Provide a resource name in the form *XUIDValue.PropertyName* and a resource value of the string that should be localized.

Custom resource lookup

For advanced scenarios, you can implement a class that can have different behavior than the XAML resource reference lookup behavior described in this topic. To do this, you implement the class CustomXamlResourceLoader, and then you can access that behavior by using the CustomResource markup extension for resource references rather

than using StaticResource or ThemeResource. Most apps won't have scenarios that require this. For more info, see CustomXamlResourceLoader.

XAML theme resources

Article • 11/26/2024

Theme resources in XAML are a set of resources that apply different values depending on which system theme is active. There are 3 themes that the XAML framework supports: "Light", "Dark", and "HighContrast".

Prerequisites: This topic assumes that you have read ResourceDictionary and XAML resource references.

Theme resources v. static resources

There are two XAML markup extensions that can reference a XAML resource from an existing XAML resource dictionary: {StaticResource} markup extension and {ThemeResource} markup extension.

Evaluation of a {ThemeResource} markup extension occurs when the app loads and subsequently each time the theme changes at runtime. This is typically the result of the user changing their device settings or from a programmatic change within the app that alters its current theme.

In contrast, a {StaticResource} markup extension is evaluated only when the XAML is first loaded by the app. It does not update. It's similar to a find and replace in your XAML with the actual runtime value at app launch.

Theme resources in the resource dictionary structure

Each theme resource is part of the XAML file themeresources.xaml. For design purposes, themeresources.xaml is available in the \(Program Files)\Windows Kits\10\DesignTime\CommonConfiguration\Neutral\UAP\<SDK version>\Generic folder from a Windows Software Development Kit (SDK) installation. The resource dictionaries in themeresources.xaml are also reproduced in generic.xaml in the same directory.

The Windows Runtime doesn't use these physical files for runtime lookup. That's why they are specifically in a DesignTime folder, and they aren't copied into apps by default. Instead, these resource dictionaries exist in memory as part of the Windows Runtime itself, and your app's XAML resource references to theme resources (or system resources) resolve there at runtime.

Guidelines for custom theme resources

Follow these guidelines when you define and consume your own custom theme resources:

- Specify theme dictionaries for both "Light" and "Dark" in addition to your "HighContrast" dictionary. Although you can create a ResourceDictionary with "Default" as the key, it's preferred to be explicit and instead use "Light", "Dark", and "HighContrast".
- Use the {ThemeResource} markup extension in: Styles, Setters, Control templates, Property setters, and Animations.
- Don't use the {ThemeResource} markup extension in your resource definitions inside your ThemeDictionaries. Use {StaticResource} markup extension instead.

  EXCEPTION: You can use the {ThemeResource} markup extension to reference resources that are agnostic to the app theme in your ThemeDictionaries. Examples of these resources are accent color resources like `SystemAccentColor`, or system color resources, which are typically prefixed with "SystemColor" like `SystemColorButtonFaceColor`.

> **⊗ Caution**
>
> If you don't follow these guidelines, you might see unexpected behavior related to themes in your app. For more info, see the **Troubleshooting theme resources** section.

The XAML color ramp and theme-dependent brushes

The combined set of colors for "Light", "Dark", and "HighContrast" themes make up the *Windows color ramp* in XAML. Whether you want to modify the system themes, or apply a theme to your own XAML elements, it's important to understand how the color resources are structured.

For additional information about how to apply color in your Windows app, please see Color in Windows apps.

Light and Dark theme colors

The XAML framework provides a set of named Color resources with values that are tailored for the "Light" and "Dark" themes. For WinUI 2, the theme resources are defined in the Common theme resources Xaml file. The color names are very descriptive of their intended usage, and there's a corresponding SolidColorBrush resource for every Color resource.

> **Tip**

For a visual overview of these colors, see the WinUI 3 Gallery app: **Colors**

> The **WinUI 3 Gallery** app includes interactive examples of most WinUI 3 controls, features, and functionality. Get the app from the Microsoft Store or get the source code on GitHub

Windows system contrast theme colors

In addition to the set of resources provided by the XAML framework, there's a set of color values derived from the Windows system palette. These colors are not specific to the Windows Runtime or Windows apps. However, many of the XAML Brush resources consume these colors when the system is operating (and the app is running) using the "HighContrast" theme. The XAML framework provides these system-wide colors as keyed resources. The keys follow the naming format: `SystemColor[name]Color`.

For more information about supporting contrast themes, see Contrast themes.

System accent color

In addition to the system contrast theme colors, the system accent color is provided as a special color resource using the key `SystemAccentColor`. At runtime, this resource gets the color that the user has specified as the accent color in the Windows personalization settings.

> **Note**
>
> While it's possible to override the system color resources, it's a best practice to respect the user's color choices, especially for contrast theme settings.

Theme-dependent brushes

The color resources shown in the preceding sections are used to set the Color property of SolidColorBrush resources in the system theme resource dictionaries. You use the brush resources to apply the color to XAML elements.

Let's look at how the color value for this brush is determined at run-time. In the "Light" and "Dark" resource dictionaries, this brush is defined like this:

```
<SolidColorBrush x:Key="TextFillColorPrimaryBrush" Color="{StaticResource TextFillColorPrimary}"/>
```

In the "HighContrast" resource dictionary, this brush is defined like this:

```
<SolidColorBrush x:Key="TextFillColorPrimaryBrush" Color="{ThemeResource SystemColorWindowTextColor}"/>
```

When this brush is applied to a XAML element, its color is determined at run-time by the current theme, as shown in this table.

Expand table

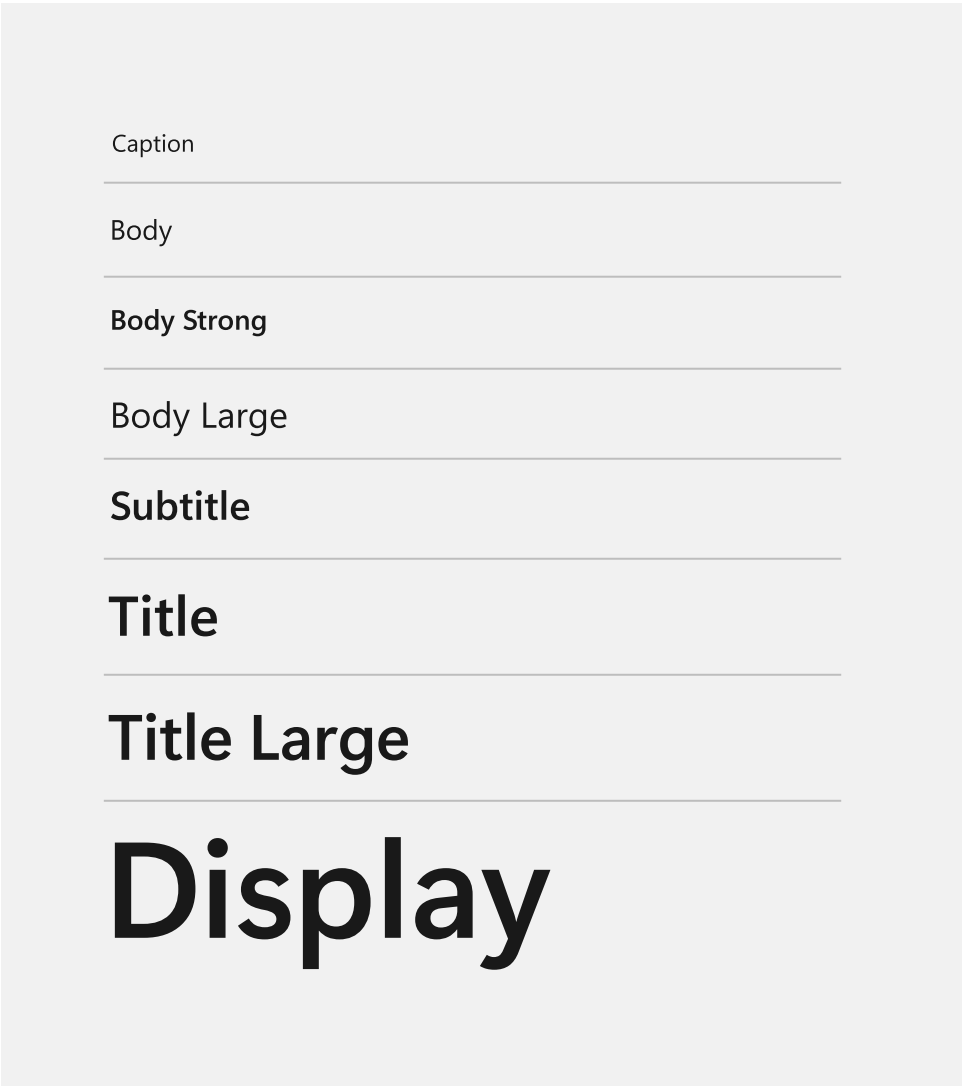
Theme	Color resource	Runtime value
Light	TextFillColorPrimary	#E4000000
Dark	TextFillColorPrimary	#FFFFFFFF
HighContrast	SystemColorWindowTextColor	The color specified in settings for Text.

The XAML type ramp

The themeresources.xaml file defines several resources that define a Style that you can apply to text containers in your UI, specifically for either TextBlock or RichTextBlock. These are not the default implicit styles. They are provided to make it easier for you to create XAML UI definitions that match the *Windows type ramp* documented in Guidelines for fonts.

These styles are for text attributes that you want applied to the whole text container. If you want styles applied just to sections of the text, set attributes on the text elements within the container, such as on a Run in TextBlock.Inlines or on a Paragraph in RichTextBlock.Blocks.

The styles look like this when applied to a TextBlock:



Expand table

Style	Weight	Size
Caption	Regular	12
Body	Regular	14
Body Strong	Semibold	14
Body Large	Regular	18
Subtitle	Semibold	20
Title	Semibold	28
Title Large	Semibold	40
Display	Semibold	68

XAML

```
<TextBlock Text="Caption" Style="{StaticResource CaptionTextBlockStyle}"/>
<TextBlock Text="Body" Style="{StaticResource BodyTextBlockStyle}"/>
<TextBlock Text="Body Strong" Style="{StaticResource
BodyStrongTextBlockStyle}"/>
<TextBlock Text="Body Large" Style="{StaticResource
BodyLargeTextBlockStyle}"/>
<TextBlock Text="Subtitle" Style="{StaticResource SubtitleTextBlockStyle}"/>
<TextBlock Text="Title" Style="{StaticResource TitleTextBlockStyle}"/>
<TextBlock Text="Title Large" Style="{StaticResource
TitleLargeTextBlockStyle}"/>
<TextBlock Text="Display" Style="{StaticResource DisplayTextBlockStyle}"/>
```

For guidance on how to use the Windows type ramp in your app, see Typography in Windows apps.

For details of the XAML styles, see WinUI on GitHub:

- Caption TextBlockStyle
- Body TextBlockStyle
- Body Strong TextBlockStyle

- Subtitle TextBlockStyle
- Title TextBlockStyle
- Title Large TextBlockStyle
- Display TextBlockStyle

Tip

For a visual overview of these styles, see the WinUI 3 Gallery app: Typography

BaseRichTextBlockStyle

TargetType: RichTextBlock

Supplies the common properties for all the other RichTextBlock container styles.

XAML

```
<!-- Usage -->
<RichTextBlock Style="{StaticResource BaseRichTextBlockStyle}">
    <Paragraph>Rich text.</Paragraph>
</RichTextBlock>

<!-- Style definition -->
<Style x:Key="BaseRichTextBlockStyle" TargetType="RichTextBlock">
```

```
    <Setter Property="FontFamily" Value="Segoe UI"/>
    <Setter Property="FontWeight" Value="SemiBold"/>
    <Setter Property="FontSize" Value="14"/>
    <Setter Property="TextTrimming" Value="None"/>
    <Setter Property="TextWrapping" Value="Wrap"/>
    <Setter Property="LineStackingStrategy" Value="MaxHeight"/>
    <Setter Property="TextLineBounds" Value="Full"/>
    <Setter Property="OpticalMarginAlignment" Value="TrimSideBearings"/>
</Style>
```

BodyRichTextBlockStyle

XAML

```
<!-- Usage -->
<RichTextBlock Style="{StaticResource BodyRichTextBlockStyle}">
    <Paragraph>Rich text.</Paragraph>
</RichTextBlock>

<!-- Style definition -->
<Style x:Key="BodyRichTextBlockStyle" TargetType="RichTextBlock" BasedOn="
{StaticResource BaseRichTextBlockStyle}">
    <Setter Property="FontWeight" Value="Normal"/>
</Style>
```

Note: The RichTextBlock styles don't have all the text ramp styles that TextBlock does, mainly because the block-based document object model for **RichTextBlock** makes it easier to set attributes on the individual text elements. Also, setting TextBlock.Text using the XAML content property introduces a situation where there is no text element to style and thus you'd have to style the container. That isn't an issue for **RichTextBlock** because its text content always has to be in specific text elements like Paragraph, which is where you might apply XAML styles for page header, page subheader and similar text ramp definitions.

Miscellaneous Named styles

There's an additional set of keyed Style definitions you can apply to style a Button differently than its default implicit style.

NavigationBackButtonNormalStyle

TargetType: Button

This Style provides a complete template for a Button that can be the navigation back button for a navigation app. The default dimensions are 40 x 40 pixels. To tailor the styling you can either explicitly set the Height, Width, FontSize, and other properties on your **Button** or create a derived style using BasedOn.

Here's a Button with the **NavigationBackButtonNormalStyle** resource applied to it.

XAML

```
<Button Style="{StaticResource NavigationBackButtonNormalStyle}" />
```

It looks like this:

NavigationBackButtonSmallStyle

TargetType: Button

This Style provides a complete template for a Button that can be the navigation back button for a navigation app. It's similar to **NavigationBackButtonNormalStyle**, but its dimensions are 30 x 30 pixels.

Here's a Button with the **NavigationBackButtonSmallStyle** resource applied to it.

XAML

```
<Button Style="{StaticResource NavigationBackButtonSmallStyle}" />
```

Troubleshooting theme resources

If you don't follow the guidelines for using theme resources, you might see unexpected behavior related to themes in your app.

For example, when you open a light-themed flyout, parts of your dark-themed app also change as if they were in the light theme. Or if you navigate to a light-themed page and then navigate back, the original dark-themed page (or parts of it) now looks as though it is in the light theme.

Typically, these types of issues occur when you provide a "Default" theme and a "HighContrast" theme to support high-contrast scenarios, and then use both "Light" and

"Dark" themes in different parts of your app.

For example, consider this theme dictionary definition:

XAML

```
<!-- DO NOT USE. THIS XAML DEMONSTRATES AN ERROR. -->
<ResourceDictionary>
  <ResourceDictionary.ThemeDictionaries>
    <ResourceDictionary x:Key="Default">
      <SolidColorBrush x:Key="myBrush" Color="{ThemeResource
ControlFillColorDefault}"/>
    </ResourceDictionary>
    <ResourceDictionary x:Key="HighContrast">
      <SolidColorBrush x:Key="myBrush" Color="{ThemeResource
SystemColorButtonFaceColor}"/>
    </ResourceDictionary>
  </ResourceDictionary.ThemeDictionaries>
</ResourceDictionary>
```

Intuitively, this looks correct. You want to change the color pointed to by `myBrush` when in high-contrast, but when not in high-contrast, you rely on the {ThemeResource} markup extension to make sure that `myBrush` points to the right color for your theme. If your app never has FrameworkElement.RequestedTheme set on elements within its visual tree, this will typically work as expected. However, you run into problems in your app as soon as you start to re-theme different parts of your visual tree.

The problem occurs because brushes are shared resources, unlike most other XAML types. If you have 2 elements in XAML sub-trees with different themes that reference the same brush resource, then as the framework walks each sub-tree to update its {ThemeResource} markup extension expressions, changes to the shared brush resource are reflected in the other sub-tree, which is not your intended result.

To fix this, replace the "Default" dictionary with separate theme dictionaries for both "Light" and "Dark" themes in addition to "HighContrast":

XAML

```
<!-- DO NOT USE. THIS XAML DEMONSTRATES AN ERROR. -->
<ResourceDictionary>
  <ResourceDictionary.ThemeDictionaries>
    <ResourceDictionary x:Key="Light">
      <SolidColorBrush x:Key="myBrush" Color="{ThemeResource
ControlFillColorDefault}"/>
    </ResourceDictionary>
    <ResourceDictionary x:Key="Dark">
      <SolidColorBrush x:Key="myBrush" Color="{ThemeResource
ControlFillColorDefault}"/>
```

```
    </ResourceDictionary>
    <ResourceDictionary x:Key="HighContrast">
      <SolidColorBrush x:Key="myBrush" Color="{ThemeResource
SystemColorButtonFaceColor}"/>
    </ResourceDictionary>
  </ResourceDictionary.ThemeDictionaries>
</ResourceDictionary>
```

However, problems still occur if any of these resources are referenced in inherited properties like Foreground. Your custom control template might specify the foreground color of an element using the {ThemeResource} markup extension, but when the framework propagates the inherited value to child elements, it provides a direct reference to the resource that was resolved by the {ThemeResource} markup extension expression. This causes problems when the framework processes theme changes as it walks your control's visual tree. It re-evaluates the {ThemeResource} markup extension expression to get a new brush resource but doesn't yet propagate this reference down to the children of your control; this happens later, such as during the next measure pass.

As a result, after walking the control visual tree in response to a theme change, the framework walks the children and updates any {ThemeResource} markup extension expressions set on them, or on objects set on their properties. This is where the problem occurs; the framework walks the brush resource and because it specifies its color using a {ThemeResource} markup extension, it's re-evaluated.

At this point, the framework appears to have polluted your theme dictionary because it now has a resource from one dictionary that has its color set from another dictionary.

To fix this problem, use the {StaticResource} markup extension instead of {ThemeResource} markup extension. With the guidelines applied, the theme dictionaries look like this:

XAML

```
<ResourceDictionary>
  <ResourceDictionary.ThemeDictionaries>
    <ResourceDictionary x:Key="Light">
      <SolidColorBrush x:Key="myBrush" Color="{StaticResource
ControlFillColorDefault}"/>
    </ResourceDictionary>
    <ResourceDictionary x:Key="Dark">
      <SolidColorBrush x:Key="myBrush" Color="{StaticResource
ControlFillColorDefault}"/>
    </ResourceDictionary>
    <ResourceDictionary x:Key="HighContrast">
      <SolidColorBrush x:Key="myBrush" Color="{ThemeResource
SystemColorButtonFaceColor}"/>
    </ResourceDictionary>
```

```
  </ResourceDictionary.ThemeDictionaries>
</ResourceDictionary>
```

Notice that the {ThemeResource} markup extension is still used in the "HighContrast" dictionary instead of {StaticResource} markup extension. This situation falls under the exception given earlier in the guidelines. Most of the brush values that are used for the "HighContrast" theme are using color choices that are globally controlled by the system, but exposed to XAML as a specially-named resource (those prefixed with 'SystemColor' in the name). The system enables the user to set the specific colors that should be used for their contrast theme settings through the Ease of Access Center. Those color choices are applied to the specially-named resources. The XAML framework uses the same theme changed event to also update these brushes when it detects they've changed at the system level. This is why the {ThemeResource} markup extension is used here.

API reference for Windows desktop apps

Article • 07/17/2024

The following collections of API frameworks can be used to build Windows desktop apps for Windows 11 and Windows 10.

Windows SDK

The Windows SDK ships with a corresponding release of the Windows OS and includes the latest headers, libraries, metadata, and tools for building Universal Windows Platform (UWP) and Win32 applications.

The following API frameworks ship with the Windows SDK:

- WinRT API reference
- WinUI 2 for UWP API reference
- Win32 API reference

Windows App SDK

The Windows App SDK provides a comprehensive set of Windows APIs with implementations that are decoupled from the operating system (OS) and the Windows SDK. The Windows App SDK ships independently as a NuGet package on a regular basis.

The following API frameworks ship with the Windows App SDK:

- WinRT API reference
- Win32 API reference
- COM interop APIs for WinUI reference
- C# Interop APIs for WinUI reference
- Bootstrapper C# APIs reference

.NET

.NET is a cross-platform, open source developer platform for building many different types of applications, including Windows desktop apps.

- .NET API reference

Schema specifications

Universal Windows Platform (UWP) apps include various file and XML schema specifications.

- Schema reference

Windows Runtime (WinRT) namespaces

Article03/22/2023

Find detailed information about Windows Runtime (WinRT) APIs.

Expand table

Namespace	Description
Windows.AI.MachineLearning	Enables apps to load machine learning models, bind features, and evaluate the results.
Windows.AI.MachineLearning.Preview	This namespace contains deprecated APIs. Please use Windows.AI.MachineLearning instead.
Windows.ApplicationModel	Provides an app with access to core system functionality and run-time information about its app package, and handles suspend operations.
Windows.ApplicationModel.Activation	Enables an app to handle the activation parameters for the activation contracts, appointments, and extensions supported by Windows.
Windows.ApplicationModel.AppExtensions	Enable your app to use content provided by other apps. Discover, enumerate, and access read-only content from those apps.
Windows.ApplicationModel.Appointments	Contains the Appointment class and related support classes. An Appointment represents an appointment in a calendar.
Windows.ApplicationModel.Appointments.AppointmentsProvider	Defines operations classes for add appointment and remove appointment requests through activations that an appointments provider interacts with.
Windows.ApplicationModel.Appointments.DataProvider	Contains the AppointmentDataProviderConnection class and support classes related to its events. An **AppointmentDataProviderConnection** allows data transfer between a Universal Windows app and the app or server that owns the calendar information of a user on the device.
Windows.ApplicationModel.AppService	Windows app services enable app-to-app communication by allowing your Universal Windows app to provide services to other Universal Windows app. App services let you create UI-less services that apps can call on the same device, and starting with Windows 10, version 1607, on remote devices.
Windows.ApplicationModel.Background	Enables an app to schedule background tasks to run app code even when the app is suspended.
Windows.ApplicationModel.Calls	Controls multiple aspects of how an application can interact with a phone device, including lock-screen

Namespace	Description
	interaction, the phone call history, and various telephony options and information.
Windows.ApplicationModel.Calls.Background	The classes in Windows.ApplicationModel.Calls.Background are used by device background tasks to handle changes to phone lines, call states, and voice mail counts for the device.
Windows.ApplicationModel.Calls.Provider	Enables an application to record and provide information about the origin of a phone call.
Windows.ApplicationModel.Chat	This namespace allows apps to implement messaging through SMS, MMS, and RCS protocols on devices that support it.
Windows.ApplicationModel.CommunicationBlocking	Enables applications to support blocking calls and messages.
Windows.ApplicationModel.Contacts	Enables apps to select and acquire info about contacts.
Windows.ApplicationModel.Contacts.DataProvider	This API is implemented by a server to provide contact information to client apps.
Windows.ApplicationModel.Contacts.Provider	Enables apps to create and remove contacts.
Windows.ApplicationModel.ConversationalAgent	Provides applications the ability to expose functionality through any digital assistant supported by the Windows Conversational Agent platform.
Windows.ApplicationModel.Core	Provides key application-level functionality for apps.
Windows.ApplicationModel.DataTransfer	Contains classes that are used to exchange data between a source app and a target app. These classes are used in share and clipboard operations.
Windows.ApplicationModel.DataTransfer.DragDrop	Manages dragging and dropping items.
Windows.ApplicationModel.DataTransfer.DragDrop.Core	Manages dragging and dropping items.
Windows.ApplicationModel.DataTransfer.ShareTarget	Contains the classes and events that a target app uses to complete share operations and create shortcuts, called QuickLinks, that the system can use to streamline future sharing operations to the app.
Windows.ApplicationModel.Email	Supports creating and interacting with email messages, recipients, and attachments.
Windows.ApplicationModel.Email.DataProvider	This API is implemented by an email server to provide email data to an email client app.
Windows.ApplicationModel.ExtendedExecution	Provides a mechanism for applications to execute when they are not in the foreground.
Windows.ApplicationModel.ExtendedExecution.Foreground	Provides a mechanism for applications to perform extended execution while they are in the

Namespace	Description
	foreground.
Windows.ApplicationModel.Holographic	Provides application model APIs for Windows Holographic apps.
Windows.ApplicationModel.LockScreen	Classes related to the Windows lock screen. Please note that creating a new lock screen is a feature **not** available to third party developers.
Windows.ApplicationModel.PackageExtensions	Enable your app to use content provided by other packages. Discover, enumerate, and access read-only content from those packages.
Windows.ApplicationModel.Payments	This namespace provides payment functionality equivalent to the W3C Payment Request API specification for Universal Windows Platform (UWP) apps. The W3C Payment Request API allows websites to collect payment information in a way that is easy for both the merchant and the user.
Windows.ApplicationModel.Payments.Provider	This namespace provides API that allow your app to facilitate payment transactions submitted by users.
Windows.ApplicationModel.Preview.Holographic	Contains classes that let apps interact with the holographic shell, allowing the user to see content in the world around them.
Windows.ApplicationModel.Preview.InkWorkspace	Provides support for specifying inking apps in the Ink Workspace.
Windows.ApplicationModel.Preview.Notes	Enables a note-taking app to implement a number of features for a faster and more effective note-taking experience in certain situations (see Remarks).
Windows.ApplicationModel.Resources	Provides simplified access to application resources, such as strings, that are defined using basic naming conventions for runtime apps.
Windows.ApplicationModel.Resources.Core	Provides classes that enable advanced resource loading.
Windows.ApplicationModel.Resources.Management	Enables the indexing of source resource files or containers, generating named resource candidates using particular file and folder naming conventions.
Windows.ApplicationModel.Search	Provides support for the search pane in apps that participate in the Search contract. The search pane opens when users activate the Search charm and provides a consistent, touch-friendly search box and optional search suggestions.
Windows.ApplicationModel.Search.Core	Provides access to search suggestions for the in-app SearchBox control and the search pane.
Windows.ApplicationModel.SocialInfo	Enables social media apps to supply feed items to Windows.

Namespace	Description
Windows.ApplicationModel.SocialInfo.Provider	Implements functionality for providing social data.
Windows.ApplicationModel.Store	Provides types and members for interacting with the Windows Store to add in-app purchases and trial functionality to your Universal Windows Platform (UWP) app.
Windows.ApplicationModel.Store.LicenseManagement	Provides APIs for managing license info for apps.
Windows.ApplicationModel.Store.Preview	Provides preview APIs for various Microsoft Store-related scenarios.
Windows.ApplicationModel.Store.Preview.InstallControl	Provides APIs for programmatically managing the installation of apps and app updates.
Windows.ApplicationModel.UserActivities	A User Activity encapsulates a user task that can be continued at a later time, and potentially on a different device.
Windows.ApplicationModel.UserActivities.Core	Manages the creation and deletion of user activities. A **UserActivity** encapsulates a user's task that can be continued at a later time, and potentially on a different device.
Windows.ApplicationModel.UserDataAccounts	Contains user data account information needed to access email, appointments, calendars, and so on.
Windows.ApplicationModel.UserDataAccounts.Provider	Enables an app to replace the existing account management and syncing functionality previously handled by the core operating system.
Windows.ApplicationModel.UserDataAccounts.SystemAccess	Provides functionality for apps to invoke system-level UI to manage sync partnerships on the device.
Windows.ApplicationModel.UserDataTasks	Enables apps to select and acquire info about tasks.
Windows.ApplicationModel.UserDataTasks.DataProvider	This API is implemented by a server to provide task information to client apps.
Windows.ApplicationModel.VoiceCommands	Provides support for handling voice commands in **Cortana**, entered by speech or text, to access features and functionality from a background app. When an app handles a voice command in the background it can display feedback on the **Cortana** canvas and communicate with the user using the **Cortana** voice.
Windows.ApplicationModel.Wallet	
Windows.ApplicationModel.Wallet.System	Defines a set of asynchronous actions and operations that manage the wallet items in the system wallet database. These can be used to read the existing items, or to add and remove items.
Windows.Data.Html	Provides utility classes for working with HTML.

Namespace	Description
Windows.Data.Json	Provides support for JSON arrays, values, and objects.
Windows.Data.Pdf	Contains classes for converting a page in a Portable Document Format (PDF) document to an image file.
Windows.Data.Text	Provides support for identifying text segments and for determining the properties of Unicode characters.
Windows.Data.Xml.Dom	Provides support for the XML Document Object Model (DOM).
Windows.Data.Xml.Xsl	Provides support for the XSLT processor.
Windows.Devices	This namespace provides access to the low level device providers, including ADC, GPIO, I^2C, PWM and SPI.
Windows.Devices.Adc	Analog-Digital Converter, or ADC, is an electrical component that converts an analog electrical signal (usually voltage) to a digital representation. ADCs usually interface a digital circuit that processes signals from analog world.
Windows.Devices.Adc.Provider	This API exposes a Provider interface for the user to implement for a specific controller. The ADC API needs a ADC Provider implementation to talk to the ADC controller.
Windows.Devices.AllJoyn	
Windows.Devices.Background	Enables the ability for device background tasks to get info provided by the app that triggered the task and to report progress back to the app.
Windows.Devices.Bluetooth	The **Windows.Devices.Bluetooth** namespace defines a set of Windows Runtime API that allows UWP app and desktop apps to interact with Bluetooth devices. For more information, see Bluetooth.
Windows.Devices.Bluetooth.Advertisement	Allow apps to send and receive Bluetooth Low Energy (LE) advertisements.
Windows.Devices.Bluetooth.Background	Provides class describing trigger details for Bluetooth triggers.
Windows.Devices.Bluetooth.GenericAttributeProfile	The **Windows.Devices.Bluetooth.GenericAttributeProfile** namespace defines Windows Runtime classes that a UWP app or a desktop application can use to communicate with Bluetooth LE devices.
Windows.Devices.Bluetooth.Rfcomm	The **Windows.Devices.Bluetooth.Rfcomm** namespace defines Windows Runtime classes that a UWP app and desktop applications can use to

Namespace	Description
	communicate with Bluetooth devices. For more information, see BluetoothTo learn more about how to use **Windows.Devices.Bluetooth.Rfcomm**, see the Bluetooth Rfcomm Chat Sample.
Windows.Devices.Custom	Opens a custom device asynchronously, and with the object returned from the open operation send asynchronous IOCTLs to the device.
Windows.Devices.Display	Contains components to determine aspects of a physical display.
Windows.Devices.Display.Core	Provides ways to manage and present content to the hardware display pipeline for custom compositor software.
Windows.Devices.Enumeration	Provides classes for enumerating devices.
Windows.Devices.Enumeration.Pnp	
Windows.Devices.Geolocation	Provides APIs for getting the current location or tracking the device's location over time. Location information may come from estimating a position from beacons like Wi-Fi access points and cell towers, from the device's IP address, or it may come from other sources such as a GNSS or GPS device. The Windows.Devices.Geolocation API provides the most appropriate geolocation data from all available sources.
Windows.Devices.Geolocation.Geofencing	A geofence is a virtual area around a geographical point. The geofencing APIs enable applications to provide geographically contextual experiences in a timely manner without the need for the app to be continuously running and consuming device resources. Geofencing enables scenarios like popping up a reminder for a user when they are leaving work or home or displaying coupons when the user gets within range of a store.
Windows.Devices.Geolocation.Provider	There are some scenarios in which the physical location of the devices isn't sufficient—either because it doesn't represent the user's real location, or the current positioning capabilities of the device aren't good enough to satisfy a particular scenario. In those cases, there's a need for a remote location source to *override* the current device location, and not only be a last resolution. The types in this namespace provide those facilities.
Windows.Devices.Gpio	Contains types for using general-purpose I/O (GPIO) pins in user mode.
Windows.Devices.Gpio.Provider	This API exposes a provider interface, and associated classes for you to implement for a specific controller.

Namespace	Description
	The GPIO API needs a GPIO provider implementation to talk to the GPIO controller.
Windows.Devices.Haptics	Provides support for basic, non-directional haptic feedback such as clicks, buzzes, and rumbles that can be tuned through characteristics such as intensity and timing.
Windows.Devices.HumanInterfaceDevice	This namespace gives your UWP app access to devices that support the Human Interface Device (HID) protocol.
Windows.Devices.I2c	Contains types that you can use to communicate with peripheral devices connected through a inter-integrated circuit (I^2C) bus from an application.
Windows.Devices.I2c.Provider	This API exposes a Provider interface and associated classes for the user to implement for a specific controller. The I2C API needs an I^2C Provider implementation to talk to the I^2C controller.
Windows.Devices.Input	Provides support for identifying the input devices available (pointer, touch, mouse, and keyboard) and retrieving information about those devices.
Windows.Devices.Input.Preview	Provide support for tracking a user's gaze, attention, and presence based on the location and movement of their eyes and head.
Windows.Devices.Lights	Provides APIs for accessing and controlling LampArrays and legacy Lamp devices.
Windows.Devices.Lights.Effects	Provides simple effects for common LampArray scenarios.
Windows.Devices.Midi	This namespace provides types for using MIDI devices in a Windows Runtime (WinRT) app.
Windows.Devices.Perception	Provides classes for handling image frames from color cameras, depth sensors, and infrared cameras.
Windows.Devices.Perception.Provider	Contains types for implementing providers of perception frames.
Windows.Devices.PointOfService	Enables application developers to access Point of Service (POS) peripheral devices. The namespace provides a vendor-neutral interface for accessing POS devices from various manufacturers from the UWP app.
Windows.Devices.PointOfService.Provider	Enables a server to provide barcode scanning functionality to client applications.
Windows.Devices.Portable	Windows Portable Devices (WPD) enables computers to communicate with attached media and storage devices. This namespace provides

Namespace	Description
	methods for identifying Windows Portable Device (WPD) services and storage.
Windows.Devices.Power	Provides APIs for detailed battery information. For more info, see Get battery information.
Windows.Devices.Printers	Provides APIs for working with 3D printers.
Windows.Devices.Printers.Extensions	Contains classes and interfaces that provide access to the Windows Runtime Components for print task configuration and print notifications.
Windows.Devices.Pwm	PWM stands for Pulse Width Modulation and describes the basic technique to create repeated square waves of user defined length and duty cycle. Most common uses include driving servo motors, dimming LEDs etc. This API provides users the ability to generate PWM wave forms using a PWM controller connected to the system.
Windows.Devices.Pwm.Provider	This API exposes a Provider interface for the user to implement for a specific controller. The PWM API needs a PWM Provider implementation to talk to the PWM controller.
Windows.Devices.Radios	The members of this namespace allow your app to find and control radio adapters, like Wi-Fi and Bluetooth, on the device where your app runs, and to query those radios for certain attributes.
Windows.Devices.Scanners	Contains the classes, interfaces, structures and other components that are built on top of the Windows Image Acquisition (WIA) COM APIs to provide scan functionality for UWP apps and desktop apps.
Windows.Devices.Sensors	Provides access to the supported types of sensors and related motion data.
Windows.Devices.Sensors.Custom	Provides access to a custom sensor and its related data.
Windows.Devices.SerialCommunication	The `Windows.Devices.SerialCommunication` namespace defines Windows Runtime classes that a UWP app can use to communicate with a device that exposes a serial port or some abstraction of a serial port. The classes provide functionality to discover such serial devices, read and write data, and control serial-specific properties for flow control, such as setting baud rate, signal states.
Windows.Devices.SmartCards	Gets info about smart card readers and smart cards; configures physical smart cards; and creates, configures, and deletes Trusted Platform Module (TPM) virtual smart cards.

Namespace	Description
Windows.Devices.Sms	Provides the ability to send and receive Short Message Service (SMS) messages, filter incoming messages, and send messages silently, as well as to query properties about a Mobile Broadband SMS Device. Use this API to implement Mobile Operator (MO) applications that use app-directed SMS to implement MO features such as visual voice mail apps.
Windows.Devices.Spi	Serial Peripheral Interface (SPI) is a high-speed interface used to communicate among integrated components on the same board.
Windows.Devices.Spi.Provider	This API exposes a Provider interface and associated classes for the user to implement for a specific controller. The SPI API needs an SPI Provider implementation to talk to the SPI controller.
Windows.Devices.Usb	This namespace defines Windows Runtime classes that a UWP app can use to communicate with WinUSB devices. These devices are handled by the inbox `winusb.sys` driver and are identified by a specific Microsoft OS Descriptor.
Windows.Devices.WiFi	
Windows.Devices.WiFiDirect	Contains classes that support connecting to associated Wi-Fi Direct devices and associated endpoints for PCs, tablets, and phones.
Windows.Devices.WiFiDirect.Services	Provides support for implementing your own Wi-Fi Direct Services.
Windows.Embedded.DeviceLockdown	Provides a simple and consistent interface for locking down the available applications and tiles on the device for specific user roles defined by the enterprise.
Windows.Foundation	Enables fundamental Windows Runtime functionality, including managing asynchronous operations and accessing property stores. This namespace also defines common value types that represent Uniform Resource Identifier (URI), dates and times, 2-D measurements, and other basic values.
Windows.Foundation.Collections	Defines standard, specialized, and generic collection objects. This includes the IIterable<T>, IVector<T> and IMap<K,V> generic interfaces, which are used as the pattern for basic collection support throughout the Windows Runtime API.
Windows.Foundation.Diagnostics	Provides classes for logging messages and tracing events.

Namespace	Description
Windows.Foundation.Metadata	Defines the attributes that indicate fundamental properties of Windows Runtime types and members.
Windows.Foundation.Numerics	Provides a set of graphics-oriented math types.
Windows.Gaming.Input	Provides access to game controller input for Windows applications.
Windows.Gaming.Input.Custom	Contains APIs enabling equipment manufacturers to write custom WinRT (Windows Runtime) class libraries for their devices.
Windows.Gaming.Input.ForceFeedback	Contains APIs for controlling the force feedback motor on a controller.
Windows.Gaming.Input.Preview	Provides APIs that support functionality for legacy gaming devices.
Windows.Gaming.Preview.GamesEnumeration	A set of APIs that provides querying installed games and their associated properties for launching and managing how a game runs in Game Mode.
Windows.Gaming.UI	Provides ways to use Game bar, game monitoring, and game chat.
Windows.Gaming.XboxLive.Storage	Contains GameSaveProvider and GameSaveContainer classes used to create, save, enumerate, and load Xbox Live game saves.
Windows.Globalization	Provides globalization support for language profiles, geographic regions, and international calendars.
Windows.Globalization.Collation	Provides read-only lists of character groupings.
Windows.Globalization.DateTimeFormatting	Enables formatting of dates and times.
Windows.Globalization.Fonts	Provides classes that allow apps to select language-appropriate and script-appropriate fonts for text display.
Windows.Globalization.NumberFormatting	Provides classes for formatting currencies, decimal numbers, percent values, and permille values, based on the user's languages and geographic region.
Windows.Globalization.PhoneNumberFormatting	Provides phone number formatting, validation, and matching with wide global support.
Windows.Graphics	Provides basic data types that contain info on how to draw graphics. These data structs are commonly used to define how large surfaces are drawn when using the CompositionVirtualDrawingSurface class.
Windows.Graphics.Capture	Enables apps to capture environments, application windows, and displays in a secure, easy to use way with the use of a system picker UI control.

Namespace	Description
Windows.Graphics.DirectX	Specifies pixel formats, and other enumerated constants, for use with Windows Runtime Direct3D 11 interop surfaces.
Windows.Graphics.DirectX.Direct3D11	Provides Windows Runtime projections of Microsoft Direct3D APIs to enable Windows Runtime applications and components to exchange Direct3D surfaces and devices.
Windows.Graphics.Display	Contains components to determine aspects of a physical display.
Windows.Graphics.Display.Core	Gets info about a display and configures their settings to support the display of your content.
Windows.Graphics.Effects	Windows.Graphics interfaces.
Windows.Graphics.Holographic	Contains classes that let apps display holograms in the world around you.
Windows.Graphics.Imaging	Enables the decoding, editing, and encoding of image files.
Windows.Graphics.Printing	Contains the classes, interfaces, structures and other components that are used by the print driver and by the Windows print system to create and manipulate documents.
Windows.Graphics.Printing.OptionDetails	Extends the basic print task options to enable you to have greater control over the printing experience that you present to your users.
Windows.Graphics.Printing.PrintSupport	Provides APIs for working with sessions of a print support settings UI.
Windows.Graphics.Printing.PrintTicket	This namespace provides Windows Runtime classes that serve as wrappers over the Print Schema COM interfaces. This allows for the easy configuration of print job instructions from within a UWP print workflow app.
Windows.Graphics.Printing.ProtectedPrint	Provides APIs related to Windows protected print mode. Windows protected print mode exclusively uses the Windows modern print stack which provides additional print security benefits on PCs. Enabling Windows protected print mode is highly recommended.
Windows.Graphics.Printing.Workflow	This namespace provides the functionality for writing a print workflow app. Print workflow apps are registered to print-capable source applications. They are launched in the background after the source application has elected to print something but before the print data is sent to the printer. Workflow apps are able to alter both the print ticket (printer device settings) and the actual content to be

Namespace	Description
	printed, and they can optionally expose this functionality to the user by launching a foreground app midway through the process. This allows for a greater degree of customization of the printing experience.
Windows.Graphics.Printing3D	Provides APIs for working with 3D printers.
Windows.Management	Provides capabilities to force a sync from an MDM device to the server. This MDM sync protocol is based on the Open Mobile Alliance - Device Management standard.
Windows.Management.Core	Provides core functionality for managing apps.
Windows.Management.Deployment	Provides functionality for managing app packages.
Windows.Management.Deployment.Preview	Provides functionality for finding installed desktop apps, and displaying their names and versions.
Windows.Management.Policies	Provides the ability for Universal Windows Platform (UWP) apps to query the current Mobile Device Management (MDM) policies on a device.
Windows.Management.Update	The types in this namespace allow users to opt in or out of receiving Windows Insider Preview builds on their device. The APIs are intended to be used by IoT original equipment manufacturers (OEMs).
Windows.Management.Workplace	Provides functionality for managing apps in an enterprise.
Windows.Media	Provides classes for creating and working with media such as photos, audio recordings and videos.
Windows.Media.AppBroadcasting	Provides APIs for getting the broadcasting status for the current app. This includes determining whether the app can currently begin broadcasting and, if not, details about why broadcasting can't be started as well as the ability to launch the app broadcasting system setup UI.
Windows.Media.AppRecording	Provides APIs for recording the audio and video content of an app to a file, saving screenshots of app content to image files, and querying the current availability of app recording and screenshot functionality.
Windows.Media.Audio	Provides APIs for routing, mixing, and processing audio.
Windows.Media.Capture	Provides classes for the capture of photos, audio recordings, and videos.
Windows.Media.Capture.Core	Provides classes for the capture of variable photo sequences.

Namespace	Description
Windows.Media.Capture.Frames	This namespace provides APIs for obtaining media frames from one or more MediaFrameSource objects representing capture devices.
Windows.Media.Casting	This namespace lets an app to cast or send particular media content to a second device and is meant to be device-protocol agnostic. Today, the APIs work with Miracast, DLNA, and Bluetooth, and support images, audio, and video from HTML Tags, ImageElement and MediaElement.
Windows.Media.ClosedCaptioning	Provides APIs for retrieving the closed caption formatting settings that the user can set through the system's closed captioning settings page.
Windows.Media.ContentRestrictions	Provides classes that define Family Safety settings for a Windows user.
Windows.Media.Control	Collection of APIs that allow control of different playback instances.
Windows.Media.Core	Contains core media APIs that are used by several different features related to media playback.
Windows.Media.Core.Preview	Provides media APIs that may be deprecated in future releases.
Windows.Media.Devices	Accesses and controls devices for audio, video, and communications.
Windows.Media.Devices.Core	Accesses and controls the device for variable photo sequences.
Windows.Media.DialProtocol	The DIAL protocol (**DI** scover **A** nd **L** aunch) lets people launches media apps from a primary device, like a phone or tablet, to a remote device like a television. See http://www.dial-multiscreen.org for more information in the industry-standard protocol.
Windows.Media.Editing	Provides functionality for editing, previewing, and saving edited media clips.
Windows.Media.Effects	Contains classes for discovering the audio processing chain on a device.
Windows.Media.FaceAnalysis	Provides APIs for face detection in bitmaps or video frames.
Windows.Media.Import	The Windows.Media.Import namespace provides APIs for discovering and importing photos and videos from devices including cameras, mass storage devices, phones, and other devices that support photo import.
Windows.Media.MediaProperties	Provides classes and other programming elements needed to create properties for media formats.

Namespace	Description
Windows.Media.Miracast	Namespace for Miracast-related functionality.
Windows.Media.Ocr	Provides optical character recognition (OCR) API for reading text from images.
Windows.Media.Playback	Provides functionality for playing media files from foreground and background tasks.
Windows.Media.Playlists	Provides classes for creating and saving media playlists for playback.
Windows.Media.PlayTo	Supports the streaming of audio, video, and images to remote devices.
Windows.Media.Protection	Provides types that provide content protection management for media content.
Windows.Media.Protection.PlayReady	Provides types that provide PlayReady content protection management for media content.
Windows.Media.Render	Provides classes for managing media rendering.
Windows.Media.SpeechRecognition	Enables speech recognition for command and control within Windows Runtime app.
Windows.Media.SpeechSynthesis	Provides support for initializing and configuring a speech synthesis engine (or voice) to convert a text string to an audio stream, also known as text-to-speech (TTS). Voice characteristics, pronunciation, volume, pitch, rate or speed, emphasis, and so on are customized through Speech Synthesis Markup Language (SSML) Version 1.1.
Windows.Media.Streaming.Adaptive	Provides the ability to playback multimedia content that is delivered using various adaptive streaming protocols. You can playback Http Live Streaming (HLS) or Dynamic Adaptive Streaming over HTTP (DASH) content.
Windows.Media.Transcoding	Contains classes for transcoding audio and video files.
Windows.Networking	Provides access to hostnames and endpoints used by network apps.
Windows.Networking.BackgroundTransfer	Enables advanced download and upload transfer capabilities within an app. For an overview of Background Transfer capabilities, see Transferring data in the background. Download the Background transfer sample for a code example.
Windows.Networking.Connectivity	Retrieves connection profiles that provide connectivity, usage, and data plan information for established network connections. This data can be used by a connected application to take appropriate action when operating in challenging network

Namespace	Description
	scenarios or abiding by data plan limits set by a network provider.
Windows.Networking.NetworkOperators	Contains classes that support Mobile Broadband Account management.
Windows.Networking.Proximity	Contains classes that support connections between devices that are within close range.
Windows.Networking.PushNotifications	Contains classes and interfaces that encapsulate push notifications.
Windows.Networking.ServiceDiscovery.Dnssd	Supports the registration and discovery of services that advertise themselves using DNS Service Discovery (DNS-SD).
Windows.Networking.Sockets	Provides sockets and WebSockets classes to use for network communications and classes for real-time network notifications received in the background for UWP apps.
Windows.Networking.Vpn	The classes in this namespace enable you to create, edit, and manage virtual private network (VPN) connections, and to write plugins for controlling a VPN connection using the Windows VPN platform.
Windows.Networking.XboxLive	This API is not available to all apps. Unless your developer account is specially provisioned by Microsoft, calls to these APIs will fail at runtime.
Windows.Perception	Contains classes for perceiving the user's surroundings, letting apps locate and reason about the device relative to the surfaces and holograms around the user.
Windows.Perception.Automation.Core	Defines support types for the Perception Automation infrastructure.
Windows.Perception.Automation.Monitoring	Defines support types for the Perception Automation Monitoring infrastructure.
Windows.Perception.People	Contains classes that describe people.
Windows.Perception.Spatial	Contains classes for reasoning about the spatial relationships within the user's surroundings.
Windows.Perception.Spatial.Preview	Contains classes that let apps track spatial nodes, allowing the user to reason about places and things in their surroundings.
Windows.Perception.Spatial.Surfaces	Contains classes that describe the surfaces observed in the user's surroundings and their triangle meshes.
Windows.Phone.ApplicationModel	Provides an app with access to core system functionality and run-time information about its app package.

Namespace	Description
Windows.Phone.Devices.Notification	The Windows.Phone.Devices.Notification namespace provides a class that you can use to notify the user by vibrating the phone.
Windows.Phone.Devices.Power	The Windows.Phone.Devices.Power namespace contains a class that provides information about the status of the phone's battery.
Windows.Phone.Management.Deployment	Provides classes to query the applications installed on a phone and manage the installation state of application packages.
Windows.Phone.Media.Devices	The Windows.Phone.Media.Devices namespace provides functionality that lets Voice over IP applications route audio to endpoints other than the speakerphone.
Windows.Phone.Networking.Voip	
Windows.Phone.Notification.Management	Provides members that allow accessories to interact with the phone.
Windows.Phone.PersonalInformation	Provides APIs for managing a custom contact store.
Windows.Phone.PersonalInformation.Provisioning	This namespace provides APIs that enable authorized entities to provision personal information.
Windows.Phone.Speech.Recognition	Enables speech recognition for Windows Phone apps.
Windows.Phone.StartScreen	Contains classes that encapsulate tile, toast, and badge notifications for dual sim devices.
Windows.Phone.System	Provides information related to system functionality.
Windows.Phone.System.Power	The Windows.Phone.System.Power namespace provides classes to indicate whether the phone's battery is in power-saving mode.
Windows.Phone.System.Profile	Contains profile information about the phone.
Windows.Phone.System.UserProfile.GameServices.Core	Provides access to game services.
Windows.Phone.UI.Core	Provides support for processing input events on the core window.
Windows.Phone.UI.Input	Provides support for user input mechanisms for the phone.
Windows.Security.Authentication.Identity	Contains classes for interacting with enterprise key credential registration.
Windows.Security.Authentication.Identity.Core	This API is for internal use only and should not be used in your code.

Namespace	Description
Windows.Security.Authentication.Identity.Provider	Supports unlocking Windows with a companion device.
Windows.Security.Authentication.OnlineId	Enables both apps and desktop programs to use Live to authenticate users by using their Microsoft account. After authentication, apps can get back a JSON token with an ID that can be used for that user with your application.
Windows.Security.Authentication.Web	Enables apps to integrate with online web services without exposing a user's credentials. The web authentication broker provides a set of APIs and infrastructure for apps to use Internet authentication and authorization protocols like OAuth and OpenID.
Windows.Security.Authentication.Web.Core	Contains core methods for obtaining tokens from web account providers.
Windows.Security.Authentication.Web.Provider	Contains classes for managing web accounts and authentication requests as an online identity provider.
Windows.Security.Authorization.AppCapabilityAccess	AppCapabilityAccess will allow for apps to request and monitor their access to Capability protected resources at runtime.
Windows.Security.Credentials	Provides a common way to securely store and manage your passcodes, passphrases, and other identification information.
Windows.Security.Credentials.UI	Enables you to use credentials without the complexity of the underlying operations, providing a uniform experience for credentials that reduces credential prompting to an absolute minimum. This namespace collects various types of credentials from users, stores them on the local computer, and presents them to web services and proxies by using existing authentication models.
Windows.Security.Cryptography	Contains a class that can be used for encoding and decoding data, generating random numbers, and converting between byte arrays and buffers.
Windows.Security.Cryptography.Certificates	Contains types that you can use to create certificate requests and install certificate responses.
Windows.Security.Cryptography.Core	Contains classes that enable you to create cryptographic keys, to hash and sign content, create message authentication codes, and to encrypt or decrypt data.
Windows.Security.Cryptography.DataProtection	Contains a class that enables you to easily encrypt and decrypt static data or a data stream.
Windows.Security.DataProtection	The Data Protection API enables data protection for all users and applications regardless of the presence

Namespace	Description
	of Windows Information Protection (WIP) policy.
Windows.Security.EnterpriseData	Contains classes that support Windows Information Protection (WIP). For the full developer picture of how WIP relates to files, buffers, the clipboard, networking, background tasks, and data protection under lock, see Windows Information Protection.
Windows.Security.ExchangeActiveSyncProvisioning	Enables an app for mail to evaluate and apply the Exchange Active Synchronization (EAS) policies.
Windows.Security.Isolation	**Deprecated.** Namespace for Windows Security Isolation APIs.
Windows.Services.Cortana	Provides types and members for accessing and managing the information an app shares with the Cortana service.
Windows.Services.Maps	The Windows.Services.Maps namespace contains classes that provide location, routing, and geocoding services.
Windows.Services.Maps.Guidance	Provides APIs for turn-by-turn guided navigation.
Windows.Services.Maps.LocalSearch	Provides APIs to search for business and places. Searches are performed against data that has been cached locally on the device.
Windows.Services.Maps.OfflineMaps	Contains classes that you can use to find and download map packages for offline use.
Windows.Services.Store	Provides types and members you can use to access and manage Microsoft Store-related data for the current app. For example, you can use this namespace to get Microsoft Store listing and license info for the current app, purchase the current app or products that are offered by the app, or download and install package updates for the app.
Windows.Services.TargetedContent	The Targeted Content namespace provides applications with the ability to subscribe to and access cloud-delivered, subscription-specific content and assets. This content is cached locally so that it is available while a device is offline. Subscription content can be updated periodically when new content is available.
Windows.Storage	Provides classes for managing files, folders, and application settings.
Windows.Storage.AccessCache	Enables and manages access to the most recently used (MRU) list of storage items, and to the list of storage items that the application has saved for efficient future access.

Namespace	Description
Windows.Storage.BulkAccess	Provides classes for searching, accessing, managing, and retrieving information about files and folders in the storage system.
Windows.Storage.Compression	Provides a unified interface to the compression features included in Windows that frees developers from responsibility for managing block sizes, compression parameters, and other details that the native compression API requires.
Windows.Storage.FileProperties	Provides access to the properties of a file.
Windows.Storage.Pickers	Provides classes for creating and managing user interface (UI) elements that let the user browse files, choose files to open, and to choose the name, extension, and location when storing files.
Windows.Storage.Pickers.Provider	Provides support for apps that offer files through the file picker by participating in the File Open Picker contract, and for apps that act as a save location for files through file picker by participating in the File Save Picker contract or the Cached File Updater contract.
Windows.Storage.Provider	Allows apps to provide real-time updates to files through the Cached File Updater contract.
Windows.Storage.Search	Provides classes for enumerating content in storage and performing Advanced Query Syntax (AQS) searches on the content.
Windows.Storage.Streams	Provides support for reading to and writing from sequential and random access streams.
Windows.System	Enables system functionality such as launching apps, obtaining information about a user, and memory profiling.
Windows.System.Diagnostics	Provides diagnostic information about the system and running processes.
Windows.System.Diagnostics.DevicePortal	Provides functionality for implementing a custom appx plugin for the Windows Device Portal.
Windows.System.Diagnostics.Telemetry	Provides functionality for registering clients with the Connected User Experience and Telemetry component.
Windows.System.Diagnostics.TraceReporting	This namespace represents the Connected User Experience and Telemetry component that manages the telemetry escalations.
Windows.System.Display	Enables an application to request that a device's display remain on even if there is no user activity for an extended period of time.

Namespace	Description
Windows.System.Implementation.FileExplorer	For internal use only.
Windows.System.Implementation.Holographic	Contains types used in the implementation of Windows components relating to the holographic shell.
Windows.System.Inventory	Provides a list of installed Win32 apps available to the current user. This includes apps installed for all users as well as only for the current user.
Windows.System.Power	Provides power and energy usage APIs.
Windows.System.Power.Diagnostics	Provides debugging APIs for computing your app's total energy usage in real time. We recommend using these APIs only for debugging.
Windows.System.Preview	Enables apps running on two panel devices to get information about the posture of the device.
Windows.System.Profile	Enables apps to get information about the system.
Windows.System.Profile.SystemManufacturers	Provides info for hardware developers and OEMs.
Windows.System.RemoteDesktop	Enables an application to obtain information about Remote Desktop sessions.
Windows.System.RemoteDesktop.Input	Provides the ability for Remote Desktop client applications to enable text input virtualization.
Windows.System.RemoteDesktop.Provider	Provides APIs for implementing remote desktop client apps.
Windows.System.RemoteSystems	Provides an app with the ability to discover and communicate with other devices. This API is part of Project Rome which allows you to create a multi-platform user experience.
Windows.System.Threading	Enables an application to use the thread pool to run work items.
Windows.System.Threading.Core	Creates work items that run in response to named events and semaphores. Also preallocates resources for work items that must be guaranteed the ability to run, even in circumstances of heavy (or full) resource allocation.
Windows.System.Update	Support for interactive control of system updates.
Windows.System.UserProfile	Enables apps get information about users, set globalization preferences, and control the lock screen image.
Windows.UI	Provides an app with access to core system functionality and run-time information about its UI.
Windows.UI.Accessibility	Provides support for working with accessibility

Namespace	Description
	devices such as screen readers and magnifiers.
Windows.UI.ApplicationSettings	Provides classes that allow developers to define the app settings that appear in the settings pane of the Windows shell. The settings pane provides a consistent place for users to access app settings.
Windows.UI.Composition	Provides APIs for user interface composition.
Windows.UI.Composition.Core	Provides core APIs for user interface composition.
Windows.UI.Composition.Desktop	Provides APIs for user interface composition.
Windows.UI.Composition.Diagnostics	Provides APIs for user interface composition diagnostics and debugging.
Windows.UI.Composition.Effects	Contains classes that are specific to creating effects for User Interactions. These effects are specific to composition.
Windows.UI.Composition.Interactions	Provides functionality that enables input driven animations in the visual layer.
Windows.UI.Composition.Scenes	Provides APIs for loading 3D models and composing 3D scenes.
Windows.UI.Core	Provides the basic user interface window components, including core input events and event dispatch.
Windows.UI.Core.AnimationMetrics	The classes and their properties that are exposed through this namespace retrieve the raw scaling, translation, and opacity parameters used in Windows animations
Windows.UI.Core.Preview	Provides preview APIs for various basic user interface window components.
Windows.UI.Core.Preview.Communications	Allows Teams or any other developer to write a plug-in VTC app for Surface Hub.
Windows.UI.Input	Provides support for the Windows input system. This includes:
Windows.UI.Input.Core	Provides support for processing input on a background thread.
Windows.UI.Input.Inking	Provides input, processing, and management support for Windows Ink apps.
Windows.UI.Input.Inking.Analysis	Provides analysis of ink stroke input for Windows Ink apps.
Windows.UI.Input.Inking.Core	Overrides default InkPresenter run-time behavior to provide advanced input, processing, and management support for Windows Ink apps.

Namespace	Description
Windows.UI.Input.Inking.Preview	Provides preview APIs for Windows Ink apps.
Windows.UI.Input.Preview	Provides Windows input preview APIs.
Windows.UI.Input.Preview.Injection	Provides support for programmatically generating and automating input from a variety of devices such as keyboard, mouse, touch, pen, and gamepad.
Windows.UI.Input.Spatial	Contains classes that let apps react naturally to your gaze, hand gestures, motion controllers and voice in the world around you.
Windows.UI.Notifications	Contains classes that encapsulate tile, toast, and badge notifications.
Windows.UI.Notifications.Management	Provides APIs for reading and managing notifications.
Windows.UI.Notifications.Preview	Provides preview APIs for Windows notification features.
Windows.UI.Popups	Provides support for context menu and message dialogs.
Windows.UI.Shell	Provides support for connecting apps with native elements of the Windows UI through the Windows Shell.
Windows.UI.StartScreen	Provides ways for apps to integrate with the Start screen, such as the creation of secondary tiles and the customization of jump lists.
Windows.UI.Text	Provides support for working with textual content.
Windows.UI.Text.Core	Provides types for accessing the Windows core text APIs and the text input server. Windows core text is a client-server system that centralizes the processing of keyboard input into a single server. You can use it to manipulate the edit buffer of your custom text input control; the text input server ensures that the contents of your text input control and the contents of its own edit buffer are always in sync via an asynchronous communication channel between the application and the server.
Windows.UI.UIAutomation	Provides support for WinRT automation clients.
Windows.UI.UIAutomation.Core	Provides types for accessing Windows core UI Automation APIs.
Windows.UI.ViewManagement	Provides support for handling and managing the various views associated with the active Universal Windows Platform (UWP) app.
Windows.UI.ViewManagement.Core	Provides support for handling and managing CoreInputView objects associated with the active

Namespace	Description
	foreground application.
Windows.UI.WebUI	Provides APIs that are specific to apps written in HTML, JavaScript, and CSS.
Windows.UI.WebUI.Core	Provides access to the command bar for apps written in HTML, JavaScript, and CSS.
Windows.UI.WindowManagement	Provides support for handling and managing the windows associated with the active app.
Windows.UI.WindowManagement.Preview	Provides preview APIs for handling and managing the windows associated with the active app.
Windows.UI.Xaml	Provides general framework APIs and application model APIs, and a variety of support classes that are commonly used by many different feature areas.
Windows.UI.Xaml.Automation	Defines the support types for Microsoft UI Automation infrastructure. These support types are for implementing Microsoft UI Automation support for a custom control. Also, AutomationProperties provides accessibility info as part of a XAML UI definition.
Windows.UI.Xaml.Automation.Peers	Contains automation peers for controls and base classes.
Windows.UI.Xaml.Automation.Provider	Defines provider patterns that are implemented by automation peers and recognized by automation clients.
Windows.UI.Xaml.Automation.Text	Contains enumerations that report specifics about text automation patterns.
Windows.UI.Xaml.Controls	Provides UI controls and classes that support existing and custom UWP controls.
Windows.UI.Xaml.Controls.Maps	Defines classes for the Map control. Also defines tile sources and elements that can be placed on a map.
Windows.UI.Xaml.Controls.Primitives	Defines classes that represent the component parts of UI controls, or otherwise support the control composition model. Also defines interfaces for control patterns such as snapping and selection.
Windows.UI.Xaml.Core.Direct	Provides XamlDirect APIs that allow middleware to access most of Xaml at a more primitive level, achieving better CPU and working set performance.
Windows.UI.Xaml.Data	Defines the data binding infrastructure for apps.
Windows.UI.Xaml.Documents	Provides basic text and document model classes.
Windows.UI.Xaml.Hosting	Provides services that are relevant for XAML design surfaces that are hosted in a larger application.

Namespace	Description
Windows.UI.Xaml.Input	Defines the input and input event infrastructure for apps and UI elements.
Windows.UI.Xaml.Interop	Provides basic types for cross-framework integration and interoperation. Notably, this includes interfaces and support types that enable binding patterns.
Windows.UI.Xaml.Markup	Provides XAML language support API for UWP app and the Windows Runtime.
Windows.UI.Xaml.Media	Provides basic media support, graphics primitives, and brush-drawing API.
Windows.UI.Xaml.Media.Animation	Provides animation and storyboard API for transition animations, visual states, or animated UI components.
Windows.UI.Xaml.Media.Imaging	Provides types related to imaging and obtaining resources and source files for bitmap images.
Windows.UI.Xaml.Media.Media3D	Contains types that support matrix/perspective transformation.
Windows.UI.Xaml.Navigation	Provides types that support navigation events as initiated by the Page and Frame classes.
Windows.UI.Xaml.Printing	Provides a basic printing support framework for applications.
Windows.UI.Xaml.Resources	Contains CustomXamlResourceLoader, which enables loading of custom resource dictionaries as sources.
Windows.UI.Xaml.Shapes	Defines basic shapes that are intended for decorative rendering or for compositing non-interactive parts of controls.
Windows.Web	Provides information on errors resulting from web service operations.
Windows.Web.AtomPub	Enables HTTP CRUD access to Web resources using the AtomPub protocol. The AtomPub sample demonstrates this implementation.
Windows.Web.Http	Provides a modern HTTP client API for UWP app.
Windows.Web.Http.Diagnostics	Provides a diagnostic facility for tracing and profiling web traffic for applications build on HTTP protocols.
Windows.Web.Http.Filters	Provides classes to send HTTP requests and an interface to create filters to target HTTP and REST services in UWP app.
Windows.Web.Http.Headers	Provides support for HTTP headers used by the Windows.Web.Http namespace for UWP app that target HTTP services.

Namespace	Description
Windows.Web.Syndication	Manages syndication feeds.
Windows.Web.UI	This namespace allows Win32 apps to host the UWP WebView control Out of Process and take full advantage of HTML5. Most of these APIs are a reflection of the Windows.UI.Xaml.Controls.WebView control.
Windows.Web.UI.Interop	This namespace allows Win32 apps to host the UWP WebView control Out of Process and take full advantage of HTML5.

Windows UWP Namespaces

Article10/03/2024

This section provides detailed information about the Windows Runtime (WinRT) APIs. These APIs are for UWP app development on Windows 10.

Expand table

Namespace	Description
Microsoft.UI.Xaml.Automation.Peers	Defines support types for the Microsoft UI Automation infrastructure.
Microsoft.UI.Xaml.Controls	Provides UI controls and classes for creating custom controls.
Microsoft.UI.Xaml.Controls.AnimatedVisuals	Defines the built-in animated visuals that can be played by an AnimatedIcon object.
Microsoft.UI.Xaml.Controls.Primitives	Defines the components that comprise WinUI controls, or otherwise support the control composition model.
Microsoft.UI.Xaml.Core.Direct	Provides a way for middleware authors to access low-level, high-performance XAML APIs and achieve better CPU and working set performance.
Microsoft.UI.Xaml.Media	Provides brushes, basic media support, and graphics primitives.
Microsoft.UI.Xaml.XamlTypeInfo	Provides support for the XAML schema.

Windows App SDK namespaces

Article03/19/2025

This section provides detailed information about the Windows Runtime (WinRT) APIs in the Windows App SDK.

Expand table

Namespace	Description
Microsoft.ApplicationModel.Resources	Provides simplified access to app resources, such as strings, that are defined using basic naming conventions.
Microsoft.Graphics.DirectX	Specifies pixel formats, and other enumerated constants, for use with Windows Runtime Direct3D 11 interop surfaces.
Microsoft.Graphics.Display	Contains components to determine aspects of a physical display.
Microsoft.Security.Authentication.OAuth	The `Microsoft.Security.Authentication.OAuth` namespace provides classes and methods for OAuth 2.0 authentication.
Microsoft.UI	Provides an app with access to core system functionality and run-time information about its UI.
Microsoft.UI.Composition	Provides APIs for user interface composition.
Microsoft.UI.Composition.Core	Provides core APIs for user interface composition.
Microsoft.UI.Composition.Diagnostics	Provides APIs for user interface composition diagnostics and debugging.
Microsoft.UI.Composition.Effects	Contains classes that are specific to creating effects for User Interactions. These effects are specific to composition.
Microsoft.UI.Composition.Interactions	Provides functionality that enables input driven animations in the visual layer.
Microsoft.UI.Composition.Scenes	Provides APIs for loading 3D models and composing 3D scenes.
Microsoft.UI.Composition.SystemBackdrops	Provides APIs for managing a CompositionBrush that defines a UI material such as Acrylic or Mica.
Microsoft.UI.Content	Provides support for defining the structure of interactive content in a Windows app through **ContentSite** (parent) and **ContentIsland** (child) objects using composition-based animations, rendering effects, user input and interactions, accessibility representation, and host state changes.
Microsoft.UI.Dispatching	Enables a queue for tasks to execute in a serial fashion on a thread.
Microsoft.UI.Input	Provides support for the Windows input system. This includes:
Microsoft.UI.Input.DragDrop	Provides support for the pointer-based, direct manipulation of an object (or data) that involves selecting that object and dragging it from one location to another location.
Microsoft.UI.Input.Interop	Provides a basic type for cross-framework input integration and inter-operation. At this time, this includes an interface and support type that expose pen device input.
Microsoft.UI.System	Windows user interface (UI) system APIs.
Microsoft.UI.Text	Provides support for working with textual content.

Namespace	Description
Microsoft.UI.Windowing	Provides support for creating and managing the windows associated with an app.
Microsoft.UI.Xaml	Provides general framework APIs for the Windows UI Library (WinUI).
Microsoft.UI.Xaml.Automation	Defines the support types for Microsoft UI Automation infrastructure. These support types are for implementing Microsoft UI Automation support for a custom control. Also, AutomationProperties provides accessibility info as part of a XAML UI definition.
Microsoft.UI.Xaml.Automation.Peers	Defines support types for the Microsoft UI Automation infrastructure.
Microsoft.UI.Xaml.Automation.Provider	Defines provider patterns that are implemented by automation peers and recognized by automation clients.
Microsoft.UI.Xaml.Automation.Text	Contains enumerations that report specifics about text automation patterns.
Microsoft.UI.Xaml.Controls	Provides UI controls and classes for creating custom controls.
Microsoft.UI.Xaml.Controls.AnimatedVisuals	Defines the built-in animated visuals that can be played by an AnimatedIcon object.
Microsoft.UI.Xaml.Controls.Primitives	Defines the components that comprise WinUI controls, or otherwise support the control composition model.
Microsoft.UI.Xaml.Data	Defines the data binding infrastructure for apps.
Microsoft.UI.Xaml.Documents	Provides basic text and document model classes.
Microsoft.UI.Xaml.Hosting	Provides services relevant to XAML design surfaces hosted in a larger application.
Microsoft.UI.Xaml.Input	Defines the input and input event infrastructure for apps and UI elements.
Microsoft.UI.Xaml.Interop	Provides basic types for cross-framework integration and interoperation. Notably, this includes interfaces and support types that enable binding patterns.
Microsoft.UI.Xaml.Markup	Provides XAML language support API for UWP app and the Windows Runtime.
Microsoft.UI.Xaml.Media	Provides brushes, basic media support, and graphics primitives.
Microsoft.UI.Xaml.Media.Animation	Provides animation and storyboard API for transition animations, visual states, or animated UI components.
Microsoft.UI.Xaml.Media.Imaging	Provides types related to imaging and obtaining resources and source files for bitmap images.
Microsoft.UI.Xaml.Media.Media3D	Contains types that support matrix/perspective transformation.
Microsoft.UI.Xaml.Navigation	Provides types that support navigation events as initiated by the Page and Frame classes.
Microsoft.UI.Xaml.Printing	Provides a basic printing support framework for applications.
Microsoft.UI.Xaml.Resources	Contains CustomXamlResourceLoader, which enables loading of custom resource dictionaries as sources.
Microsoft.UI.Xaml.Shapes	Defines basic shapes that are intended for decorative rendering or for compositing non-interactive parts of controls.

Namespace	Description
Microsoft.UI.Xaml.XamlTypeInfo	Provides support for the XAML schema.
Microsoft.Windows.ApplicationModel.Background	The **Microsoft.Windows.ApplicationModel.Background** APIs support background task registration for apps that leverage Windows App SDK.
Microsoft.Windows.ApplicationModel.Background.UniversalBGTask	The **Microsoft.Windows.ApplicationModel.Background.UniversalBGTask** APIs support background task registration for apps that leverage Windows App SDK.
Microsoft.Windows.ApplicationModel.DynamicDependency	Provides the ability for unpackaged desktop apps to load framework packages other than the Windows App SDK framework package. After the specified framework package is loaded by an unpackaged desktop app, the app can call APIs provided by the framework package.
Microsoft.Windows.ApplicationModel.Resources	Provides simplified access to app resources, such as strings, that are defined using basic naming conventions.
Microsoft.Windows.ApplicationModel.WindowsAppRuntime	Provides access to deployment information for the Windows App SDK runtime and the ability to register any missing packages for the runtime.
Microsoft.Windows.AppLifecycle	Provides APIs you can use to manage the lifecycle of your app. For example, you can control whether multiple instances of your app's process can run at the same time, and you can receive information about different kinds activations for your app.
Microsoft.Windows.AppNotifications	This namespace provides APIs for managing app notifications.
Microsoft.Windows.AppNotifications.Builder	Provides APIs for programmatically generating the XML payload for an AppNotification.
Microsoft.Windows.BadgeNotifications	Contains classes that support badge notifications.
Microsoft.Windows.Globalization	Provides globalization support (such as language profiles) for apps built with the Windows App SDK.
Microsoft.Windows.Management.Deployment	This namespace provides MSIX package management APIs comparable to those in the Windows.Management.Deployment namespace, but with additional functionality, improved developer experience, and performance optimizations.
Microsoft.Windows.Media.Capture	Provides APIs for configuring an launching the CameraCaptureUI which allows the user to capture photos, videos, or both.
Microsoft.Windows.PushNotifications	This namespace provides APIs for managing push notifications that use the Windows Push Notification Service (WNS).
Microsoft.Windows.Security.AccessControl	Contains APIs that ease and streamline named object sharing between packaged apps and Win32 applications.
Microsoft.Windows.Storage	Contains APIs in the Microsoft.Windows.Storage namespace that are available to access storage resources from Windows apps.
Microsoft.Windows.System	Contains APIs in the Microsoft.Windows.System namespace that are available to access system resources from Windows apps.
Microsoft.Windows.System.Power	Provides a set of power management APIs that allow visibility into how an app affects the device's power state, and enable the app to make intelligent decisions about resource usage. For example, an app might use this API to postpone resource-intensive background tasks while the device is running on battery power.

Namespace	Description
Microsoft.Windows.Widgets	Provides APIs related to Windows widgets.
Microsoft.Windows.Widgets.Feeds.Providers	Provides APIs for implementing a feed provider for Windows feeds.
Microsoft.Windows.Widgets.Notifications	
Microsoft.Windows.Widgets.Providers	Provides APIs for implementing a widget provider for Windows Widgets.

Bootstrapper C++ API

Article • 06/03/2022

The Bootstrapper C++ API is a set of types and functions (callable only from C++) that offer an alternative way to call the Bootstrapper API.

Topics in this section

Expand table

Topic	Description
Constants for use with the Bootstrapper C++ API	The following constants (for use with the Bootstrapper C++ API) are declared in `WindowsAppSDK-VersionInfo.h`.
Microsoft::Windows::ApplicationModel namespace	Types and functions from the Bootstrapper C++ API that are in the (**Microsoft::Windows**) **ApplicationModel** namespace. For example, a class that represents a version of the Windows App SDK framework package.
Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap namespace	Types and functions from the Bootstrapper C++ API that are in the (**Microsoft::Windows::ApplicationModel::DynamicDependency**) **Bootstrap** namespace. For example, helper functions that wrap calls to the Bootstrapper API.

Constants for use with the Bootstrapper C++ API

Article • 04/19/2023

The following constants (for use with the Bootstrapper C++ API) are declared in `WindowsAppSDK-VersionInfo.h`.

Microsoft::WindowsAppSDK::Release namespace

Expand table

Constant	Value	Description
constexpr PCWSTR Channel	[release-dependent]	The Windows App SDK release's channel; for example, L"preview", or empty string for stable.
constexpr PCWSTR FormattedVersionShortTag	[release-dependent]	The Windows App SDK release's short-form version tag, formatted for concatenation when constructing identifiers; for example, "-p2", or empty string for stable.
constexpr PCWSTR FormattedVersionTag	[release-dependent]	The Windows App SDK release's version tag, formatted for concatenation when constructing identifiers; for example, "-preview2", or empty string for stable.
constexpr uint16_t Major	[release-dependent]	The major version of the Windows App SDK release.
constexpr uint32_t MajorMinor	[release-dependent]	The major and minor version of the Windows App SDK release, encoded as a uint32_t (0xMMMMNNNN where M=major, N=minor).
constexpr uint16_t Minor	[release-dependent]	The minor version of the Windows App SDK release.
constexpr uint16_t Patch	[release-dependent]	The patch version of the Windows App SDK release.
constexpr PCWSTR VersionShortTag	[release-dependent]	The Windows App SDK release's short-form version tag; for example, L"p2", or empty string for stable.
constexpr PCWSTR VersionTag	[release-dependent]	The Windows App SDK release's version tag; for example, L"preview2", or empty string for stable.

Microsoft::WindowsAppSDK::Runtime::Identity namespace

Expand table

Constant	Value	Description
constexpr PCWSTR	L"CN=Microsoft Corporation, O=Microsoft	The Windows App SDK runtime's

Constant	Value	Description
Publisher	Corporation, L=Redmond, S=Washington, C=US"	package identity's Publisher.
constexpr PCWSTR PublisherId	L"8wekyb3d8bbwe"	The Windows App SDK runtime's package identity's PublisherId.

Microsoft::WindowsAppSDK::Runtime::Packages::Framewc namespace

Expand table

Constant	Value	Description
constexpr PCWSTR PackageFamilyName	"Microsoft.WindowsAppRuntime.1.1-preview1_8wekyb3d8bbwe"	The Windows App SDK runtime's Framework package's family name.

Microsoft::WindowsAppSDK::Runtime.Packages.DDLM.Arr namespace

Expand table

Constant	Value	Description
constexpr PCWSTR PackageFamilyName	[release-dependent]	The Windows App SDK runtime's Dynamic Dependency Lifetime Manager (DDLM) package's family name, for arm64.

Microsoft::WindowsAppSDK::Runtime.Packages.DDLM.X64 namespace

Expand table

Constant	Value	Description
constexpr PCWSTR PackageFamilyName	[release-dependent]	The Windows App SDK runtime's Dynamic Dependency Lifetime Manager (DDLM) package's family name, for x64.

Microsoft::WindowsAppSDK::Runtime.Packages.DDLM.X86 namespace

Expand table

Constant	Value	Description
constexpr PCWSTR PackageFamilyName	[release-dependent]	The Windows App SDK runtime's Dynamic Dependency Lifetime Manager (DDLM) package's family name, for x86.

Microsoft::WindowsAppSDK::Runtime::Packages::Main namespace

Expand table

Constant	Value	Description
constexpr PCWSTR PackageFamilyName	L"MicrosoftCorporationII.WinAppRuntime.Main.1.1-p1_8wekyb3d8bbwe"	The Windows App SDK runtime's Main package's family name.

Microsoft::WindowsAppSDK::Runtime::Packages::Singleton namespace

Expand table

Constant	Value	Description
constexpr PCWSTR PackageFamilyName	L"Microsoft.WindowsAppRuntime.Singleton-preview1_8wekyb3d8bbwe"	The Windows App SDK runtime's Singleton package's family name.

Microsoft::WindowsAppSDK::Runtime::Version namespace

Expand table

Constant	Value	Description
constexpr uint16_t Build	[release-dependent]	The build version of the Windows App SDK runtime; for example, 804.
constexpr PCWSTR DotQuadString	[release-dependent]	The version of the Windows App SDK runtime, as a string (const wchar_t*); for example, L"1000.446.804.0".
constexpr uint16_t Major	[release-dependent]	The major version of the Windows App SDK runtime; for example, 1000.
constexpr uint16_t Minor	[release-dependent]	The minor version of the Windows App SDK runtime; for example, 446.
constexpr uint16_t Revision	[release-dependent]	The revision version of the Windows App SDK runtime; for example, 0.
constexpr uint64_t UInt64	[release-dependent]	The version of the Windows App SDK runtime, as a uint64l for example, 0x03E801BE03240000.

Requirements

Minimum supported SDK: Windows App SDK version 1.1

Namespace: Microsoft::WindowsAppSDK

Header: WindowsAppSDK-VersionInfo.h

Microsoft::Windows::ApplicationModel namespace

Article • 06/03/2022

Types and functions from the Bootstrapper C++ API that are in the **Microsoft::Windows::ApplicationModel** namespace. For example, a class that represents a version of the Windows App SDK framework package.

Types in the Microsoft::Windows::ApplicationModel namespace

Expand table

Type	Description
PackageVersion class	Represents a version of the Windows App SDK framework package.

See also

Bootstrapper C++ API

PackageVersion class

Article • 04/19/2023

Represents a version of the Windows App SDK framework package.

Syntax

```
C++

class PackageVersion : public PACKAGE_VERSION;
```

Requirements

Minimum supported SDK: Windows App SDK version 1.1

Namespace: Microsoft::Windows::ApplicationModel

Header: MddBootstrap.h

Constructors

Expand table

Constructor	Description
PackageVersion constructor	Initializes a new instance of the **PackageVersion** class.

Member functions

Expand table

Function	Description
PackageVersion::ToString function	Retrieves the version as a **std::wstring**.
PackageVersion::ToVersion function	Retrieves the version as a **uint64_t**.

PackageVersion::PackageVersion constructor

Initializes a new instance of the **PackageVersion** class.

Syntax

```
C++
```

```
PackageVersion();
PackageVersion(uint16_t major, uint16_t minor = 0, uint16_t build = 0,
uint16_t revision = 0);
PackageVersion(uint64_t version);
```

Parameters

`major` A **uint16_t** value representing the `major` position of a `major.minor.build.revision` sequence.

`minor` An optional **uint16_t** value representing the `minor` position of a `major.minor.build.revision` sequence. Defaults to 0.

`build` An optional **uint16_t** value representing the `build` position of a `major.minor.build.revision` sequence. Defaults to 0.

`revision` An optional **uint16_t** value representing the `revision` position of a `major.minor.build.revision` sequence. Defaults to 0.

`version` A `major.minor.build.revision` sequence encoded as a (little-endian) **uint64_t** (so that the first 16 bits contain the revision, and so on).

PackageVersion::ToString function

Retrieves the version as a **std::wstring**.

Syntax

```
C++
```

```
std::wstring ToString() const;
```

Return value

The `major.minor.build.revision` sequence encoded as a string (**std::wstring**) in the format "12345.12345.12345.12345" + null-terminator.

PackageVersion::ToVersion function

Retrieves the version as a **uint64_t**.

Syntax

```
C++
```

```
uint64_t ToVersion() const;
```

Return value

The `major.minor.build.revision` sequence encoded as a (little-endian) **uint64_t** (so that the first 16 bits contain the revision, and so on).

See also

- Microsoft::Windows::ApplicationModel namespace

Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap namespace

Article • 06/03/2022

Types and functions from the Bootstrapper C++ API that are in the **Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap** namespace. For example, helper functions that wrap calls to the Bootstrapper API.

Functions in theMicrosoft::Windows::ApplicationModel::DynamicDependency:: namespace

Expand table

Function	Description
Initialize function	Calls MddBootstrapInitialize to initialize the calling process to use the specified version of the Windows App SDK's framework package. If the call fails, throws an exception.
InitializeFailFast function	Calls MddBootstrapInitialize to initialize the calling process to use the specified version of the Windows App SDK's framework package. If the call fails, aborts the process (via **std::abort**).
InitializeNoThrow function	Calls MddBootstrapInitialize to initialize the calling process to use the specified version of the Windows App SDK's framework package. If the call fails, returns a failure **HRESULT**.

See also

Bootstrapper C++ API

Initialize function

Article • 04/19/2023

Calls MddBootstrapInitialize to initialize the calling process to use the specified version of the Windows App SDK's framework package. If the call fails, throws an exception.

Syntax

C++

```
inline auto Initialize(
    uint32_t majorMinorVersion = WINDOWSAPPSDK_RELEASE_MAJORMINOR,
    PCWSTR versionTag = WINDOWSAPPSDK_RELEASE_VERSION_TAG_W,
    PackageVersion minVersion = WINDOWSAPPSDK_RUNTIME_VERSION_UINT64)
```

Parameters

`majorMinorVersion` See *majorMinorVersion* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RELEASE_MAJORMINOR.

`versionTag` See *versionTag* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RELEASE_VERSION_TAG_W.

`minVersion` See *minVersion* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RUNTIME_VERSION_UINT64.

Return value

On success, returns a resource acquisition is initialization (RAII) object which, when it goes out of scope, undoes the changes that were made by the call to MddBootstrapInitialize.

Example

C++

```
#include <windows.h>

#include <winrt\base.h>

#include <WindowsAppSDK-VersionInfo.h>
#include <MddBootstrap.h>
```

```
#include <iostream>

namespace MddBootstrap {using namespace
    ::Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap; }

int main()
{
    try
    {
        auto mddBootstrapCleanup{ MddBootstrap::Initialize() };
        // Do work here.
    }
    catch (const winrt::hresult_error& ex)
    {
        const auto hr{ ex.code() };
        std::cout << "Error 0x" << std::hex << hr << " in Bootstraper
initialization";
        return hr;
    }
    return 0;
}
```

Requirements

Minimum supported SDK: Windows App SDK version 1.1

Namespace: Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap

Header: MddBootstrap.h

See also

InitializeFailFast function

Article • 04/19/2023

Calls MddBootstrapInitialize to initialize the calling process to use the specified version of the Windows App SDK's framework package. If the call fails, aborts the process (via **std::abort**).

Syntax

C++

```
inline auto InitializeFailFast(
    uint32_t majorMinorVersion = WINDOWSAPPSDK_RELEASE_MAJORMINOR,
    PCWSTR versionTag = WINDOWSAPPSDK_RELEASE_VERSION_TAG_W,
    PackageVersion minVersion = WINDOWSAPPSDK_RUNTIME_VERSION_UINT64)
```

Parameters

`majorMinorVersion` See *majorMinorVersion* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RELEASE_MAJORMINOR.

`versionTag` See *versionTag* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RELEASE_VERSION_TAG_W.

`minVersion` See *minVersion* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RUNTIME_VERSION_UINT64.

Return value

On success, returns a resource acquisition is initialization (RAII) object which, when it goes out of scope, undoes the changes that were made by the call to MddBootstrapInitialize.

Example

C++

```
#include <windows.h>

#include <WindowsAppSDK-VersionInfo.h>
#include <MddBootstrap.h>
```

```
#include <iostream>

namespace MddBootstrap {using namespace
    ::Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap; }

int main()
{
    auto mddBootstrapShutdown{ MddBootstrap::InitializeFailFast() };
    // Do work here.
    return 0;
}
```

Requirements

Minimum supported SDK: Windows App SDK version 1.1

Namespace: Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap

Header: MddBootstrap.h

See also

- Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap namespace
- MddBootstrapInitialize

InitializeNoThrow function

Article • 04/19/2023

Calls MddBootstrapInitialize to initialize the calling process to use the specified version of the Windows App SDK's framework package. If the call fails, returns a failure **HRESULT**.

Syntax

C++

```
inline auto Initialize(
    uint32_t majorMinorVersion = WINDOWSAPPSDK_RELEASE_MAJORMINOR,
    PCWSTR versionTag = WINDOWSAPPSDK_RELEASE_VERSION_TAG_W,
    PackageVersion minVersion = WINDOWSAPPSDK_RUNTIME_VERSION_UINT64)
```

Parameters

`majorMinorVersion` See *majorMinorVersion* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RELEASE_MAJORMINOR.

`versionTag` See *versionTag* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RELEASE_VERSION_TAG_W.

`minVersion` See *minVersion* in MddBootstrapInitialize. Defaults to WINDOWSAPPSDK_RUNTIME_VERSION_UINT64.

Return value

On success, returns **S_OK**. If the call to MddBootstrapInitialize fails, returns a failure **HRESULT**.

Example

C++

```
#include <windows.h>

#include <WindowsAppSDK-VersionInfo.h>
#include <MddBootstrap.h>

#include <iostream>
```

```
namespace MddBootstrap {using namespace
    ::Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap; }

int main()
{
    const auto hr{ MddBootstrap::InitializeNoThrow() };
    if (FAILED(hr))
    {
        std::cout << "Error 0x" << std::hex << hr << " in Bootstrap
initialization";
        return hr;
    }
    auto mddBootstrapShutdown{ MddBootstrap::unique_mddbootstrapshutdown(
            reinterpret_cast<MddBootstrap::details::mddbootstrapshutdown_t*>
(1)
        ) };
    // Do work here.
    return 0;
}
```

Requirements

Minimum supported SDK: Windows App SDK version 1.1

Namespace: Microsoft::Windows::ApplicationModel::DynamicDependency::Bootstrap

Header: MddBootstrap.h

See also

WinUI COM Interop

Article07/14/2023

To develop with COM interop APIs for WinUI, you need these headers:

- microsoft.ui.xaml.hosting.desktopwindowxamlsource.h
- microsoft.ui.xaml.hosting.referencetracker.h
- microsoft.ui.xaml.media.dxinterop.h
- microsoft.ui.xaml.window.h
- xamlom.winui.h

For programming guidance for this technology, see WinUI 3.

Enumerations

XAML_REFERENCETRACKER_DISCONNECT

Functions

AddMemoryPressure Informs the host of increased memory allocations since the last notification.
AddRefFromReferenceTracker Indicates that the reference tracker is returning the target XAML object(s) from previous calls to FindTrackerTargets.
AddRefFromTrackerSource Indicates each time that a tracker source calls **IUnknown::AddRef** on the reference tracker (called after **AddRef**).
BeginDraw
BeginDraw

ConnectFromTrackerSource Indicates that a reference tracker source has created its first COM reference on a reference tracker object.
CreateTrackerHandle
DeleteTrackerHandle
DisconnectFromTrackerSource Indicates that a reference tracker source has stopped tracking a reference tracker.
DisconnectUnusedReferenceSources Requests that the host perform garbage collection and remove all unnecessary reference sources.
EndDraw
EndDraw
FindTrackerTargets Finds the reference tracker targets that are reachable from a reference tracker source.
FindTrackerTargetsCompleted Indicates that a garbage collection system has finished making all the calls it needs to IReferenceTracker::FindTrackerTargets (by this time, XAML has pegged all reference tracker targets that it wants to protect).
FlushAllSurfacesWithDevice
FoundTrackerTarget Called whenever a XAML object reference tracker target is found.
get_WindowHandle Retrieves the window handle (**HWND**) of the window represented by the object that implements IWindowNative.
GetReferenceTrackerManager

Gets an IReferenceTrackerManager interface from a XAML object.
GetTrackerTarget Requests the host provide a reference tracker target that references a reference tracker source. This tracker target then controls the lifetime of the tracker source.
GetUiLayerForXamlRoot Gets the visual diagnostics root that can be used to draw on for highlighting elements in the tree.
GetUpdateRectCount
GetUpdateRects
GetVisibleBounds
HitTestForXamlRoot Gets all elements in the visual tree that fall within the specified rectangle.
Invalidate
NotifyEndOfReferenceTrackingOnThread Notifies the host that reference tracking is no longer available on the calling thread; XAML calls this when the **FrameworkView** is uninitialized.
OnXamlRootChange Communicates when a XamlRoot root is added or removed.
Peg Marks that the reference tracker target is in use by the XAML framework, and should not be collected.
PegFromTrackerSource Indicates that a tracker source is unable to protected a reference tracker object.
ReferenceTrackingCompleted Indicates that a garbage collection system has finished with its collection process (at this point, XAML unblocks threads attempting to update tracked references).

ReferenceTrackingStarted Indicates that a garbage collector is performing a collection.
RegisterForUpdatesNeeded
ReleaseDisconnectedReferenceSources Requests that the host call **IUnknown::Release** on any reference tracker objects that have been disconnected by a reference source.
ReleaseFromReferenceTracker Releases the XAML object reference marked in a previous call to AddRefFromReferenceTracker.
ReleaseFromTrackerSource Indicates each time that a tracker source calls **IUnknown::Release** on the reference tracker (must be called before the **Release** call).
RemoveMemoryPressure Informs the host of reduced memory allocations since the last notification.
Resize
ResumeDraw
SetDevice
SetDevice
SetReferenceTrackerHost Registers an IReferenceTrackerHost interface with XAML.
SetSwapChain
SetSwapChain
SetSwapChainHandle

SetTrackerValue
SuspendDraw
TryGetSafeTrackerValue
Unpeg Marks that the reference tracker target is no longer in use by the XAML framework and can be collected.
UpdatesNeeded

Interfaces

IFindReferenceTargetsCallback Defines the interface for callbacks from FindTrackerTargets.
IReferenceTracker Defines the interface implemented by the XAML framework for managing XAML object references.
IReferenceTrackerExtension
IReferenceTrackerHost Defines an interface that provides the global services used by the garbage collection (GC) system used by the XAML framework.
IReferenceTrackerManager Defines the interface for a XAML object reference manager. Implement this interface to manage instances of IReferenceTracker on XAML objects.
IReferenceTrackerTarget Defines an interface implemented by a garbage collector object referenced from XAML.

ISurfaceImageSourceManagerNative
ISurfaceImageSourceNative
ISurfaceImageSourceNativeWithD2D
ISwapChainBackgroundPanelNative
ISwapChainPanelNative
ISwapChainPanelNative2
ITrackerOwner
IVirtualSurfaceImageSourceNative
IVirtualSurfaceUpdatesCallbackNative
IVisualTreeServiceCallback3 Represents additional capabilities of an IVisualTreeServiceCallback2 object.
IWindowNative Enables interoperability between XAML and a native window.
IXamlDiagnostics2 Represents additional capabilities of an IXamlDiagnostics object.

Interop C# APIs for WinUI

Article • 10/24/2022

As a C# desktop application developer, in .NET you can make use of C# interop classes whose methods wrap and represent several interoperability functions. These include methods of C# classes representing the GetWindowIdFromWindow function, for example.

These C# interop classes are available in .NET as part of the Windows App SDK.

Win32Interop.GetDisplayIdFromMonitor(IntPtr) method

Article • 10/24/2022

Reference

Definition

Namespace: Microsoft.UI

Gets the `DisplayId` that corresponds to the specified *hmonitor*, if the provided `hmonitor` is valid.

C#

```
public static DisplayId GetDisplayIdFromMonitor(IntPtr hmonitor);
```

Parameters

`hmonitor` IntPtr

The handle of the display monitor for which to get the `DisplayId`.

Returns

DisplayId

The display monitor identifier that corresponds to the specified *hmonitor*, if the provided *hmonitor* is valid. Otherwise, `null`.

Win32Interop.GetIconFromIconId(IconId) method

Article • 10/24/2022

Reference

Definition

Namespace: Microsoft.UI

Gets the icon handle that corresponds to the specified *iconId*, if the provided *iconId* is valid and the system has an `HICON` that represents the icon.

C#

```
public static IntPtr GetIconFromIconId(IconId iconId);
```

Parameters

`iconId` IconId

The identifier for the icon.

Returns

IntPtr

The icon handle that corresponds to the specified *iconId*, if the provided *iconId* is valid and the system has an `HICON` that represents the icon. Otherwise, `null`.

Constants for use with the Bootstrapper C# APIs

Article • 11/23/2022

The following constants are for use with the Bootstrapper C# APIs.

Definition

Namespace: **Microsoft.WindowsAppSDK**

Assembly: Microsoft.WindowsAppRuntime.Release.Net.dll

Microsoft.WindowsAppSDK.Release class

Expand table

Constant	Value	Description
public const string Channel	[release-dependent]	The Windows App SDK release's channel; for example, "preview", or empty string for stable.
public const string FormattedVersionShortTag	[release-dependent]	The Windows App SDK release's short-form version tag, formatted for concatenation when constructing identifiers; for example, "-p2", or empty string for stable.
public const string FormattedVersionTag	[release-dependent]	The Windows App SDK release's version tag, formatted for concatenation when constructing identifiers; for example, "-preview2", or empty string for stable.
public const ushort Major	[release-dependent]	The major version of the Windows App SDK release.
public const uint MajorMinor	[release-dependent]	The major and minor version of the Windows App SDK release, encoded as a uint32_t (0xMMMMNNNN where M=major, N=minor).
public const ushort Minor	[release-dependent]	The minor version of the Windows App SDK release.
public const ushort Patch	[release-dependent]	The patch version of the Windows App SDK release.
public const string VersionShortTag	[release-dependent]	The Windows App SDK release's short-form version tag; for example, "p2", or empty string for stable.
public const string VersionTag	[release-dependent]	The Windows App SDK release's version tag; for example, "preview2", or empty string for stable.

Microsoft.WindowsAppSDK.Runtime.Identity class

Expand table

Constant	Value	Description
public const string Publisher	"CN=Microsoft Corporation, O=Microsoft Corporation, L=Redmond, S=Washington, C=US"	The Windows App SDK runtime's package identity's Publisher.
public const string PublisherId	"8wekyb3d8bbwe"	The Windows App SDK runtime's package identity's PublisherId.

Microsoft.WindowsAppSDK.Runtime.Packages.DDLM.Arm class

Expand table

Constant	Value	Description
public const string PackageFamilyName	[release-dependent]	The Windows App SDK runtime's Dynamic Dependency Lifetime Manager (DDLM) package's family name, for arm64.

Microsoft.WindowsAppSDK.Runtime.Packages.DDLM.X64 class

Expand table

Constant	Value	Description
public const string PackageFamilyName	[release-dependent]	The Windows App SDK runtime's Dynamic Dependency Lifetime Manager (DDLM) package's family name, for x64.

Microsoft.WindowsAppSDK.Runtime.Packages.DDLM.X86 class

Expand table

Constant	Value	Description
public const string PackageFamilyName	[release-dependent]	The Windows App SDK runtime's Dynamic Dependency Lifetime Manager (DDLM) package's family name, for x86.

Microsoft.WindowsAppSDK.Runtime.Packages.Framework class

Expand table

Constant	Value	Description
public const string PackageFamilyName	"Microsoft.WindowsAppRuntime.1.1-preview1_8wekyb3d8bbwe"	The Windows App SDK runtime's Framework package's family name.

Microsoft.WindowsAppSDK.Runtime.Packages.Main class

Expand table

Constant	Value	Description
public const string PackageFamilyName	"MicrosoftCorporationII.WinAppRuntime.Main.1.1-p1_8wekyb3d8bbwe"	The Windows App SDK runtime's Main package's family name.

Microsoft.WindowsAppSDK.Runtime.Packages.Singleton class

Expand table

Constant	Value	Description
public const string PackageFamilyName	"Microsoft.WindowsAppRuntime.Singleton-preview1_8wekyb3d8bbwe"	The Windows App SDK runtime's Singleton package's family name.

Microsoft.WindowsAppSDK.Runtime.Version class

Expand table

Constant	Value	Description
public const ushort Major	[release-dependent]	The major version of the Windows App SDK runtime; for example, 1000.
public const ushort Minor	[release-dependent]	The minor version of the Windows App SDK runtime; for example, 446.
public const ushort Build	[release-dependent]	The build version of the Windows App SDK runtime; for example, 804.
public const ushort Revision	[release-dependent]	The revision version of the Windows App SDK runtime; for example, 0.
public const ulong UInt64	[release-dependent]	The version of the Windows App SDK runtime, as a uint64l for example, 0x03E801BE03240000.
public const string DotQuadString	[release-dependent]	The version of the Windows App SDK runtime, as a string (const wchar_t*); for example, "1000.446.804.0".

Bootstrap class

Article • 04/19/2023

The **Bootstrap** class contains static helper methods that conveniently wrap calls to the Bootstrapper API.

Definition

Namespace: Microsoft.Windows.ApplicationModel.DynamicDependency

Assembly: Microsoft.WindowsAppRuntime.Bootstrap.Net.dll

```
C#
```

```
public class Bootstrap
```

Methods

- Initialize methods
- Shutdown()
- TryInitialize methods

Initialize methods

Initializes the calling process to use Windows App SDK's framework package. Finds a Windows App SDK framework package meeting the criteria provided in the arguments, and makes it available for use by the current process. If multiple packages meet the criteria, then the best candidate is selected.

```
C#
```

```
public static void Initialize(uint majorMinorVersion);
public static void Initialize(uint majorMinorVersion, string versionTag);
public static void Initialize(uint majorMinorVersion, string versionTag,
PackageVersion minVersion);
```

Parameters

`majorMinorVersion` uint

The major and minor version of the Windows App SDK framework package to load. The version is encoded as `0xMMMMNNNN`, where `M` = Major and `N` = Minor (for example, version 1.2 should be encoded as `0x00010002`).

`versionTag` string

The version tag of the Windows App SDK framework package to load (if any). For example, `"prerelease"`. Defaults to `null`.

`minVersion` PackageVersion

The minimum version of the Windows App SDK framework package to use. Defaults to a new default instance of **PackageVersion**.

Shutdown method

Removes the changes made to the current process by Initialize or TryInitialize. After **Shutdown** is called, your app can no longer call Windows App SDK APIs, including the Dynamic dependency API.

C#

```
public static void Shutdown();
```

TryInitialize methods

Initializes the calling process to use Windows App SDK's framework package. Failure returns false with the failure **HRESULT** in the *hresult* parameter. Finds a Windows App SDK framework package meeting the criteria provided in the arguments, and makes it available for use by the current process. If multiple packages meet the criteria, then the best candidate is selected.

C#

```
public static bool TryInitialize(uint majorMinorVersion, out int hresult);
public static bool TryInitialize(uint majorMinorVersion, string versionTag,
out int hresult);
public static bool TryInitialize(uint majorMinorVersion, string versionTag,
PackageVersion minVersion, out int hresult);
```

Parameters

`majorMinorVersion` uint

The major and minor version of the Windows App SDK framework package to load. The version is encoded as `0xMMMMNNNN`, where `M` = Major and `N` = Minor (for example, version 1.2 should be encoded as `0x00010002`).

`hresult` uint

The failure **HRESULT**, if the initialization failed.

`versionTag` string

The version tag of the Windows App SDK framework package to load (if any). For example, `"prerelease"`. Defaults to `null`.

`minVersion` PackageVersion

The minimum version of the Windows App SDK framework package to use. Defaults to a new default instance of **PackageVersion**.

PackageVersion struct

Article • 04/19/2023

Represents a version of the Windows App SDK framework package.

Definition

Namespace: Microsoft.Windows.ApplicationModel.DynamicDependency

Assembly: Microsoft.WindowsAppRuntime.Bootstrap.Net.dll

C#

```
public struct PackageVersion
```

Constructors

- PackageVersion constructors

Fields

- Build
- Major
- Minor
- Revision

Methods

- ToString()
- ToVersion()

PackageVersion constructors

Initializes a new instance of the **PackageVersion** class.

C#

```
public PackageVersion(ushort major);
public PackageVersion(ushort major, ushort minor);
```

```
public PackageVersion(ushort major, ushort minor, ushort build);
public PackageVersion(ushort major, ushort minor, ushort build, ushort
revision);
public PackageVersion(ulong version);
```

Parameters

`major` ushort

The `major` position of a `major.minor.build.revision` sequence.

`minor` ushort

The `minor` position of a `major.minor.build.revision` sequence. Defaults to 0.

`build` ushort

The `build` position of a `major.minor.build.revision` sequence. Defaults to 0.

`revision` ushort

The `revision` position of a `major.minor.build.revision` sequence. Defaults to 0.

`version` ulong

A `major.minor.build.revision` sequence encoded as a (little-endian) **UInt64** (so that the first 16 bits contain the revision, and so on).

Build field

Gets or sets the `build` position of a `major.minor.build.revision` sequence.

```
C#
```

```
public ushort Build;
```

Major field

Gets or sets the `major` position of a `major.minor.build.revision` sequence.

```
C#
```

```
public ushort Major;
```

Minor field

Gets or sets the `minor` position of a `major.minor.build.revision` sequence.

```
C#

public ushort Minor;
```

Revision field

Gets or sets the `revision` position of a `major.minor.build.revision` sequence.

```
C#

public ushort Revision;
```

ToString method

Retrieves the version as a string.

```
C#

public override string ToString();
```

Returns

string

The `major.minor.build.revision` sequence encoded as a string.

ToVersion method

Retrieves the version as a **UInt64**.

```
C#

public ulong ToVersion();
```

Returns

ulong

The `major.minor.build.revision` sequence encoded as a (little-endian) **UInt64** (so that the first 16 bits contain the revision, and so on).

File and XML schema specifications for UWP apps

Article • 12/13/2019

This section provides information about file and XML schema specifications for Universal Windows Platform (UWP) apps.

Topic	Description
App Installer file	An App Installer file is an XML document (*.appinstaller) that contains app package and bundle information for defining the packages that are part of a related set.
App package block map	The package block map file is an XML document that contains a list of the app's files along with indexes and cryptographic hashes for each block of data that is stored in the package.
App package manifest	Includes reference topics that describe the schema used for packaging Windows apps.
Application content schema	The Application content, or appcontent-ms, schema for Windows apps enables developers to enhance in-app search by providing extra information about your app's content to the Windows Search Index.
Bundle manifest	The bundle manifest file is an XML document that contains a list of app packages and resource packages in the bundle. Includes reference topics that describe the schema used for packaging bundles.
Final content group map	The final content group map file is an XML document (AppxContentGroupMap.xml) that contains automatic content groups for UWP app streaming install.
Schema for Mobile Broadband	Includes reference topics that describe the schema used to provision a mobile broadband enabled device on a mobile broadband network, query subscriber data usage information, or query the results of the last provisioning attempt.
Source content group map	The source content group map file is an XML document (SourceAppxContentGroupMap.xml) that contains required and automatic content groups for UWP app streaming install.
StoreManifest schema	Includes reference topics that describe the schema used by developers to enable optional Store features that the AppxManifest.xml file does not cover.
Tiles, toast, and badge schemas	Includes reference topics that describe the underlying schemas used for tiles, toast notifications, and badges.

Topic	Description
Cortana Voice command (VCD) schemas	Reference topics that describe the XML markup elements and attributes used in Voice Command Definition (VCD) files to specify recognition constraints.
